Attention is called to the results immediately adjacent to the fixed bench marks; namely:

From	To	Difference, in feet by survey
TX	1	12.84
1	TX	12.84
SZ	3	19.63
3	SZ	19.64
NY	5	17.09
5	NY	17.10

A common inference is that the correct differentials between the foregoing bench marks are 12.84, 19.635, and 17.095, respectively, and many surveyors would start their adjustment of the net on this assumption. The computation of all corrections simultaneously shows the fallacy in this reasoning, as the most probably correct differentials prove to be 12.83, 19.66, and 17.08.

Inasmuch as the final elevations in this case are only to the nearest 0.01 ft, slide-rule computations were used throughout.

The writer agrees that the slight additional time required to adjust a circuit is well worth while and hopes that the average surveyor will be helped to grasp the mechanical process by the additional specific example set forth in this discussion. Acknowledgment is made to Mr. Speert for his suggestions as to the application of the new method to this typical example.

GEORGE D. WHITMORE,[13] M. AM. SOC. C. E., C. C. MINER,[14] ASSOC. M. AM. SOC. C. E., AND W. O. BYRD,[15] ESQ. (by letter).—The method of traverse and level adjustment described by the authors is correctly termed an "improved" and "simplified" method. Since April, 1939, these methods have been used consistently by the computing personnel of the Tennessee Valley Authority (TVA), to the exclusion of all other methods, for all traverse and level surveys of third-order or less accuracy. The authors infer, and the writers agree, that the described method may not always be ideally suited for adjustment of "most precise geodetic traverse" (first-order accuracy), since in traverse control of such precision, it is not always feasible to assume that all closure errors remaining after an azimuth adjustment are accidental errors of latitude and departure. In the cases of first-order and second-order level networks, the TVA computers continue to use the least-squares procedure recommended by the U. S. Coast and Geodetic Survey.

A point which always should be included in a paper on surveys adjustments is this: If the results of a traverse survey are to be published for use by other organizations and individuals, it is suggested that an inverse computation should always be made for each course of the traverse, from the finally adjusted coordinates of each pair of adjacent traverse stations, to determine an azimuth and a distance for each course which will agree exactly with the published adjusted coordinates. Otherwise, the preliminary or unadjusted azimuth and distance usually will disagree slightly with the values computed from adjusted coordinates, often to the confusion of the casual user of the traverse survey.

[13] Chf. of Surveys, Maps and Surveys Div., TVA, Chattanooga, Tenn.

[14] Chf. Computer, TVA, Chattanooga, Tenn.

[15] Asst. in Chg. of Computing, TVA, Chattanooga, Tenn.

The writers concur with the authors' statements that: (1) Results by the "improved" method are identical with results by the conventional least-squares method; (2) results by the "improved" method usually seem more logical and more consistent than results by the junction-point method; and (3) the labor involved in using the "improved" method is not greater and is often less than the labor required for any cruder method.

The writers are glad to note that the authors have stressed the use of a diagram as a desirable preliminary of this method. A detailed diagram showing the magnitude and signs of closures, direction of closures, length of line, or other data fixing weights, is almost an absolute prerequisite in any method of adjustment. As emphasized by the authors, such a diagram shows at once the lines having largest closures, and the locations of lines most likely to contain the large errors. Most really experienced survey computers appreciate this and make use of adjustment diagrams accordingly. There is a decided tendency among inexperienced computers, however, to try to work without a diagram on which all essential data are shown. Hence they often become hopelessly confused and end with results far different from those which the mere inspection of a diagram would reveal to be the most logical. If it does nothing else, the diagram gives the computer an over-all or "bird's-eye view" of the system which he is adjusting—certainly a desirable thing if the computer is to do any more than mere mechanical work.

The use of the number of set-ups in a traverse line as the basis for the weight of line, in contrast to using the length of line, appears to be a desirable improvement. The writer often has used a weight which would fall about midway between the weight determined by length and by the number of set-ups. In this connection, it would appear that no harm would result from rounding off each weight value to the nearest single decimal place, although, of course, in the solution itself the terms must be extended to the proper number of decimals. The authors suggest that where level control lines are parallel to the traverse lines, corrections can be determined through one solution for both the traverse coordinates and the elevations. In such a case, the use of the number of instrument set-ups in each traverse line as the basis for its weight may not always prove to give the most logical weight for the parallel level line. Computers who face the situation of paralleling traverse and level lines should consider, thoroughly, this matter of best weights for each type of survey before combining the level and traverse adjustments in one solution. For instance, in adjusting levels, the weight for each line could be based, conceivably, on any one or any combination of the following: (1) The number of level-instrument set-ups; (2) the total difference of elevation (including both uphill and downhill); (3) the length of the line; (4) the average length of sight; or (5) (as suggested in the paper) the number of transit stations in the parallel traverse line.

The unique feature of the method described appears to be in the use of the unadjusted position or elevation value at each junction point, instead of in the attempt to determine first an approximately adjusted value which will lie quite near the finally adjusted results. Through this procedure, a considerable portion of the "assumed-minus-observed" terms becomes zero, thus greatly reducing the number of operations and making the adjustment more completely adaptable to machine computation. It is found that by using the adjustment diagrams as recommended by the authors, the adjustment equations of the "improved" method can be tabulated from the diagram immediately, thus eliminating the necessity for preparing the usual auxiliary and correlate tables of the conventional least-squares procedure.

It is found, as stated by the authors, that the mechanics of this improved method are very simple and can be grasped quickly even by freshmen cooperative students who have had no previous computing experience. The writers have adjusted or caused to be adjusted many hundreds of miles of both traverse and levels by using this "improved" method, and recommend it in every way.

ROBERT C. SHELDON,[16] ASSOC. M. AM. SOC. C. E. (by letter).—As progress in engineering and surveying increases the need for, and use of, coordinate systems of surveying, in which all traverses are closed on points with fixed positions, the need for a satisfactory method of adjusting the closing errors of the traverse nets is correspondingly increased. The method presented in the paper fills this need admirably. It was the writer's first thought that any method that used the typical Doolittle method for the solution of the necessary simultaneous equations would be too difficult for the average engineering office to use. The authors, however, have so simplified the preliminary work of forming the equations as to make the method easy to use by any office with a computing machine.

The writer has applied the method on a traverse net that had previously been adjusted by another method. The net contained five fixed stations and eight interior junctions. The previous adjustment had been by what might be called "the single-line" method, or "path-of-least-resistance" method. That is, the field data between two fixed stations were computed into latitude and longitude increments in feet, after which the errors of closure at the second fixed station were distributed over the traverse in proportion to the lengths of the courses. After this distribution, the points on the line were considered as fixed stations and any lines starting or ending on them were adjusted to close.

The fixed points were triangulation stations that had been placed and adjusted so that, without question, their accuracy was of a higher degree than 1 : 10,000. The field methods used in running the traverses were such that accuracies of 1 : 10,000 could have been expected and 1 : 5,000 was required. The lines running between the fixed stations were well within the requirements, but several of the ties between the interior junction points were not.

The corrections to the traverses, to make them close on the fixed points, or junction points, by the single-line method were: Minimum 1 : 9,000, maximum 1 : 3,000, and the average over the net 1 : 6,000. After adjustment by the authors' method, the corrections to the traverses to make them close on the adjusted junction points were: Minimum 1 : 20,000 (except one line practically precise closure), maximum 1 : 5,000, and average over the entire net 1 : 11,000. The adjustment was made using the field values and not those found by the previous adjustment.

---

[16] Asst. Engr., Section of Surveys, The Panama Canal, Balboa, Canal Zone.

The time required in making the adjustment by the authors' method was a matter of hours. With experienced men, this adjustment on a net of this size would seldom require more than two days. The time lost in unsuccessful attempts to find errors in the field and office work on the traverses that did not close, using the single-line method, was a matter of several days.

The writer is in complete agreement with the conclusions of the authors and believes that the method presented will be a valuable aid to any engineering or surveying organization using a coordinate method of surveying. The writer's application of the method was made on the Panama Canal system using degrees, minutes, and feet of both latitude and longitude rather than the northing and eastings used by the authors.

CLARENCE NORRIS,[17] ESQ., AND JULIUS L. SPEERT,[18] ASSOC. M. AM. SOC. C. E. (by letter).—The comments of those who have discussed the paper have added vital information to it and have greatly increased its value to surveyors. A number of questions have been raised, also, which justify further discussion.

The writers cannot conceal their gratification at the unanimity with which most of those who have discussed the paper welcome the new method of adjustment. Although the method has withstood the test of use by the computers of the U. S. Geological Survey, as mentioned by Mr. Wilson, and its merit has been fully demonstrated, it was feared that its simplicity might be so hidden by the complex instructions required to present it that its real value might be lost.

There can be no question that, at first glance, the new method appears complex, and it was anticipated that the claims that it "is so simple as to be easily understood by any one familiar with the elements of surveying and of algebra" and that "a complete adjustment can be made by a clerk familiar with the use of the computing machine" would provoke disagreement. However, the experience of the Tennessee Valley Authority (TVA), as presented by Messrs. Whitmore, Miner, and Byrd, that the method was used satisfactorily "even by freshmen cooperative students who have had no previous computing experience," is a strong argument in support of these claims. The ease with which the method can be mastered is further attested by the experience of the Geological Survey. During the past few years, several computers who have come into the office have grasped the method apparently without difficulty. These men have included recent engineering graduates, a few college graduates with a knowledge of mathematics but no training in engineering or surveying, and a few older field men who have had relatively little mathematical background or have been out of school so long as to have lost all familiarity with it. In each instance, the mechanics of the adjustment were so readily acquired as to justify the writers' claim of simplicity.

---

[17] Asst. Topographic Engr., U. S. Geological Survey, Washington, D. C.

[18] Asst. Topographic Engr., U. S. Geological Survey, Washington, D. C.

In spite of all this, it was not the writers' intention to recommend that adjustments be left entirely in the hands of a clerk. However, it is believed that, under competent engineering supervision, the mechanics of the adjustment can be performed quite satisfactorily by untrained personnel.

The slide-rule solution of the equations suggested by Mr. Dell appears to be an excellent substitute for the Doolittle solution in those adjustments for which slide-rule precision is adequate, particularly for the adjustment of a level net. For a traverse adjustment, however, the entire process would have to be performed twice, and it appears that a single solution by the Doolittle method, even by slide rule, might be quicker.

Mr. Dell's recommendation that the Doolittle method of solving equations be incorporated in the mathematics requirements of engineering students suggests the desirability of including the theory of this method of adjustment in the surveying courses of such students. Because of its complexity and mathematical background, the method of least squares is not, so far as the writers are aware, taught to engineers except in advanced courses in geodesy or mathematics. The principle of weighted means, however, is so basic and simple that even a student of elementary surveying should be able to grasp it and appreciate its significance. Having once absorbed the theory of adjustment, even if the mechanics of the solution have been long forgotten, an engineer should have relatively little difficulty in making a simple adjustment if called on to do so in later years. Then the predicament described by Mr. Coe of searching "many texts without success for a simple method of adjustment for a series of interlocking traverses" could, to an extent, be avoided.

Messrs. Whitmore, Miner, and Byrd, like several of the others, recognize that results by the new method are identical with those by the conventional least-squares methods. Nevertheless, they seem to limit its use by the TVA to surveys of third-order limits or lower, and for first-order and second-order levels continue to use the longer methods described by the U. S. Coast and Geodetic Survey. The writers wonder why this should be so. Although the new method is not recommended for first-order traverse, it is fully adequate for adjusting the most precise levels. It must be emphasized that the new method is equally as "exact" as the conventional least-squares methods, the only difference being that the approach to the normal equations has been "streamlined."

They also suggest that an inverse computation be made to correct the azimuth and length of each course to agree with the adjusted coordinates of its ends. For this purpose, the writers propose the following modification of the formulas used in correcting triangulation lines after readjustment of datum:[11]

$$da = K\,(dE \cos a - dN \sin a) \dots\dots\dots\dots\dots\dots (19)$$

and

$$ds = dN \cos a + dE \sin a \dots\dots\dots\dots\dots\dots (20)$$

In these formulas, dN and dE are the adjustment corrections at the beginning of a course, A, minus those at the other end, B, in feet; K, in seconds, is $\frac{1}{s \sin 1''} = \frac{206{,}300}{s}$; K, in minutes, is $\frac{1}{s \sin 1'} = \frac{3{,}438}{s}$; a is the observed azimuth from A to B; s is the measured length of the course, in feet; and da and ds

are the corrections to be applied to a and s, respectively, to bring them into agreement with the adjusted coordinates of A and B. The quantities da and ds will always be so small that slide-rule computation will afford ample precision. If a number of lines are to be adjusted by these formulas, preparation of a simple computing form would help to standardize the work and save time.

Mr. Dell makes the interesting observation that, in this method, at least one station in the survey must be treated as a fixed point. In an isolated survey, where no "fixed point" is available, any one station may be assigned an arbitrary adjustment correction (preferably zero), and all other adjustment corrections may be referred to that assumed datum. If, later, a more satisfactory datum is established, the entire system may then be shifted by a uniform correction to fit the new datum.

A somewhat similar interesting problem recently came to the attention of the writers. A third-order traverse net was tied at several places to an old first-order traverse line and also to several triangulation stations. The triangulation was on the 1927 North American Datum, but the traverse line was on an old datum and, with the data available, could not be brought to the 1927 datum for the purpose of controlling the adjustment of the third-order net. It was desired to adjust the new traverse to the 1927 North American Datum, and still give the first-order line all the influence in the adjustment to which it was entitled. In other words, the first-order line could not be used to control the datum of the new traverse, but relative positions along its route were to be held as fixed by its original adjustment. Thus, the old line was free to be translated, but could not be distorted by the new adjustment. This was accomplished in the adjustment by treating all ties to the first-order line as if made to a single junction, this junction to receive an adjustment correction the same as any other in the third-order net. This had the effect of including the first-order line in the adjustment, and of giving its sections infinite weight, but at the same time allowing it perfect freedom in shifting its datum. By this procedure, all ties to the first-order line received the same datum correction and were brought to the 1927 North American Datum, and no distorting adjustment corrections were thrown into the parts of the first-order line.

Mr. Rappleye suggested that a sample of a level-net adjustment should have been included in the paper. It is hoped that the adjustment presented by Mr. Coe will fill that need. Although Mr. Coe's example may not be truly a "net," it has all the elements of a larger adjustment and fully illustrates the principles. In this connection, a few points in Mr. Coe's rules relating to Table 11 should be clarified. In the solution of the equations, the N- and S-columns must be carried down simultaneously with the body of the table in order to provide a check on each line before proceeding with the next line. Otherwise, a mistake in the solution may pass undetected and affect some of the subsequently computed values. In other words, rules 10 and 11 should follow immediately after rule 2. Similarly, rules 8 and 9 should be combined with rule 6, emphasizing that the c-factor used is always taken from the column of the principal term of the equation being formed.

Mr. Dell raises a vital point concerning the importance of careful determination of weight factors for the lines of a survey net, and Table 7 gives striking evidence of this importance. As brought out by Mr. Dell and several others, the proper weight of a line is a very complicated function of a large number of uncertain, and at present unmeasurable, factors. It might even appear, at a casual glance, that careful adjustment by any "precise" method is an unwarranted refinement so long as such uncertainty exists in the determination of weights. The problem of weights, however, enters into all methods of adjustment in about the same way, so that, strictly speaking, the matter of determining weights is not involved in the method used in making the adjustment. It appears that, whether weights are assigned in accordance with the simple rules suggested or whether a more complex procedure is used to include other factors involved, a reasonable adjustment may be expected if all the elements of the survey are properly balanced against one another. The importance of including all the elements of a survey in a general adjustment, rather than adjusting line by line, is illustrated by the example presented by Mr. Sheldon. Nevertheless, the writers agree that the determination of weights is perhaps the weakest factor that enters into an adjustment, and a practical means of evaluating all the uncertainties involved is much to be desired.

The wide applicability of this method of adjustment is illustrated by the variety of problems mentioned in the discussion. The traverse example in the paper was presented in terms of feet of northing and easting; the traverse of the Geological Survey, described by Mr. Wilson, is computed and adjusted in terms of degrees, minutes, and seconds of latitude and longitude; the surveys of the Panama Canal system, discussed by Mr. Sheldon, use degrees, minutes, and feet of latitude and longitude. Similarly, in levels, Mr. Coe's example is adjusted in foot units, and the adjustments mentioned by Mr. Rappleye are in metric units. Inasmuch as the units of measurement enter the adjustment only in the absolute columns, and as the absolute columns of an adjustment are not interdependent, it is not even essential that the same units be used in both columns. Thus, the fact that a second of latitude is different in length from a second of longitude does not interfere with a simultaneous adjustment of both. Similarly, under proper circumstances, seconds of latitude and longitude and feet or meters of elevation could be included in the same adjustment.

In conclusion, the writers wish to express their sincere gratitude to all those who have discussed the paper for the interest they have shown and for the valuable suggestions and comments offered.

Paper No. 2088

FLASH-BOARD PINS

By Chilton A. Wright,[1] and Clifford A. Betts,[2]
Members, Am. Soc. C. E.

With Discussion by Messrs. William P. Creager, Lincoln W. Ryder, E. T. Schuleen, John E. Field, Julian H. White, Harry H. Hatch, and Chilton A. Wright and Clifford A. Betts.

Synopsis

Formulas and stress values for the design of pipe supports on the automatic flash-board gates of dam spillways are developed and discussed in this paper. As a result of hydraulic laboratory tests of full-size flash-boards, supplemented by mechanical tests of the pipe supports and check tests of actual field installations outlined herein, data have been obtained which permit accurate predetermination of the lake level at which gates of this type will automatically fall and by-pass flood water.

In addition to the description of the tests and the analysis of the relations between water head, height of flash-boards, and size and spacing of pipe, the results have been consolidated to serve as a guide in the design of flash-board installations. On this basis the United States Forest Service has designed hinged flash-board gates, supported by steel pipes, and has installed them on a number of their dams. Field tests, made at these dams later, yielded results that closely check the laboratory tests.

Flash-Boards

Automatic flash-board gates are a logical development of the conventional flash-board for reservoir water-surface regulation. Being a structure that increases the height of a dam, usually on the spillway section (see Fig. 1), the flash-board is designed to fail under a predetermined head of water and fall, thereby increasing the flood-carrying capacity of the spillway. In the past many flash-board installations have been constructed, using light, inexpensive planks, supported by closely spaced pins, and were lost after failure during a

---

Note.—Published in May, 1939, *Proceedings*.

flood. Many other types of flash-boards have been used in which failure was induced mechanically by cutting anchor wires or posts or by lifting with traveling hoists.

Conservation of the storage at the top of a reservoir, where every foot of additional depth represents the cream of the storage, is of high economic value during dry periods, particularly on water-power and water-supply projects. On numerous streams where spring floods are followed by extended periods of low flow, flash-boards can be raised toward the end of the high-water stage and the storage can be augmented for carrying through the drought period. Control of water-surface fluctuations within narrow limits is advantageous and sometimes imperative for fish and game lakes, as well as on recreational developments. As a "safety valve" against back-water overflow or sustained inundation, flash-boards are distinctly effective. In arid regions conservation of water usually requires hand gates, but in humid regions where the flood menace, rather than the water loss, is the prime consideration, the cost of hand-operated flood gates is not justified when the same function can be performed by simple, automatic flash-board gates.

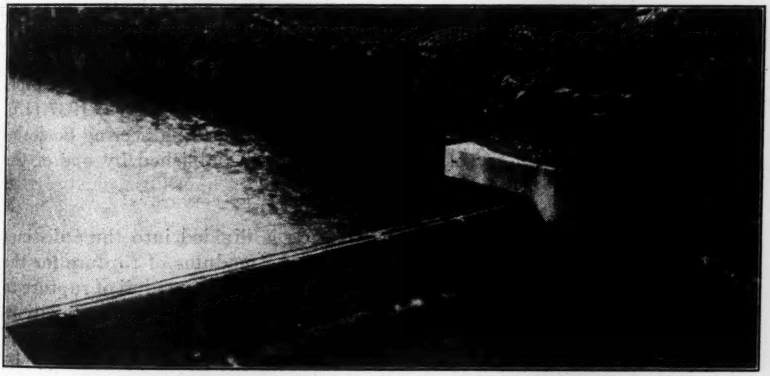

FIG. 1.—HINGED AUTOMATIC FLASH-BOARD GATE, 2.5 FEET HIGH BY 35 FEET LONG, AT LAKE SHERANDO DAM, GEORGE WASHINGTON NATIONAL FOREST

The cost of providing flash-boards is small compared with that of increasing the size of the spillway. In many cases it is almost prohibitive to provide spillway capacity, adequate to handle rare yet disastrous floods, unless flash-boards are used. For the control of large floods, a deep spillway gate can be constructed in multiple panels which will fall successively, thereby limiting the discharge in the channel below, except for exceptional floods, and using the pondage to equalize the flow.

Flash-boards of plank may be converted into flash-board gates by the addition of hinges and stiffening members of wood or steel. The entire structure can be made of wood, steel, or other structural material. After the flood the gates may simply be raised again and the broken supports replaced.

By providing dependable regulation at low cost, thereby protecting not only the dam but also the property below and the lake shores above, the automatic flash-board gate becomes an important factor in water conservation.

NECESSITY FOR TESTS

Such use of flash-boards presupposes failure of the supporting pipe within narrow limits of reservoir water level. Positive failure of the flash-boards is essential to successful operation, inasmuch as the entire dam is in danger if the flash-boards do not function as designed. Region Seven of the U. S. Forest Service had the problem of providing flash-boards for a number of earth dams similar to that shown in Fig. 1, where certain action of the flash-boards was essential.

A search of the published literature[3] for data to be used in the general design of supports for flash-board installations yielded only a few isolated tests of pins, made during construction, and gave no assurance that the pins or pipes would fail reasonably near the desired water head. In fact, discrepancies of 2 ft, or 50%, were obtained by using stresses suggested by different writers.

Thus, tests were required to furnish dependable design data. The Forest Service suggested and co-operated in a series of tests made in the National Hydraulic Laboratory, National Bureau of Standards, on various types and sizes of flash-boards, mounted on a low dam crest, and supported by pins consisting of various sizes of standard commercial steel and wrought iron pipe. A complete report of these tests was prepared under date of April, 1937 (15). A copy of this report has been filed for reference in the Engineering Societies Library.[4] A brief summary of the test results was published by one of the writers in 1936 (16).

SCOPE OF INVESTIGATION

Hydraulic Tests.—The general investigation is divided into three distinct parts: (a) The experimental determination of the modulus of rupture for the pipes used to support the flash-boards; (b) the use of these moduli of rupture to compute the head or water level at which various flash-board installations should fail, using various simplified moment formulas for this purpose; and (c) the comparison of these computed heads with the heads at which failure actually occurs in various flash-board installations in order to determine the accuracy with which the various moment formulas can be used.

The hydraulic tests were made of pipe ranging from $\frac{3}{4}$ in. to 3 in. in size (see Table 1). Spacing between the pipes was varied from 5 to 8 ft. The wider spacing of the larger pipes was found necessary in order that they might collapse under the limited water head available in the laboratory flume. The flash-boards ranged from 1 ft 10 in. to 5 ft 2 in. in height above the dam crest. In addition to measuring the water elevations above and below the dam, and deflections of the pipe under load, its behavior prior to, and after, the yield point was reached was observed. Panels about 3.5 ft by 5 ft having "V" joints and "butt" joints were tried before concentrating the tests on continuous flash-boards fastened together to operate as a single unit.

---

[3] See bibliography in Appendix I. Line numbers in parentheses are used to indicate references.

[4] 33 West Thirty-Ninth Street, New York, N. Y.

The moduli of rupture were computed from these tests and formulas developed for design. Then, as a ready means of checking the formulas, the laboratory set-up was assumed to be a field installation, the formulas were applied thereto, and their accuracy was judged by comparison with the test results.

Mechanical Tests.—In order to determine whether simple mechanical tests could be substituted for the more elaborate hydraulic tests and still yield the equivalent necessary values of modulus of rupture, samples were cut from the pipes used in the hydraulic tests. These specimens were tested as cantilevers in a testing machine, and the results were compared with those derived from the hydraulic tests.

Pipe vs. Solid Pins.—Tests made on solid steel pins prior to these pipe tests had revealed certain inherent disadvantages of the solid type. A small variation in diameter, composition, or heat treatment made a relatively large change in load capacity—a striking contrast to the pipe behavior (from previous tests made for the Forest Service by the National Bureau of Standards). Furthermore, extensive tests on mild steel pins by the Pennsylvania Water and Power Company of Baltimore, Md., indicated that the solid pins continued to deflect and carry load until they had deflected nearly 90 degrees.

DESCRIPTION OF EXPERIMENTS

Hydraulic Tests

General Layout.—The hydraulic tests were made in the main concrete flume on the first floor of the National Hydraulic Laboratory (see Fig. 2). It is 12 ft by 12 ft in cross-section, and was supplied with water by three pumps having a combined capacity of 35 cu ft per sec. The pumps discharged into a concrete tank about 25 ft by 32 ft in section, at the upper end of the flume, as shown in Fig. 3. Two motor-operated gates, 6 ft square, were used to control the flow into the flume. During most of the tests, a bulkhead, built for use in another investigation, was present in the flume down stream from the experimental set-up, but finally it was removed to prevent the tail-water from rising too rapidly during the tests. A large drain was provided in the side of the flume down stream from the flash-boards to return the water to the supply basin below the floor.

About 52 ft down stream from the control gates, a concrete dam crest, 21 in. high and about 28 ft long, equivalent to the crest of an actual dam, was constructed across the flume. To obtain this length, it was necessary to place the crest diagonally as shown in Fig. 2. For the preliminary experiments, five flash-boards, each 5 ft long and 3 ft 6 in. high, were placed on the crest and were supported by pipes of the same diameter placed in sockets embedded in the crest of the dam at 5-ft intervals.

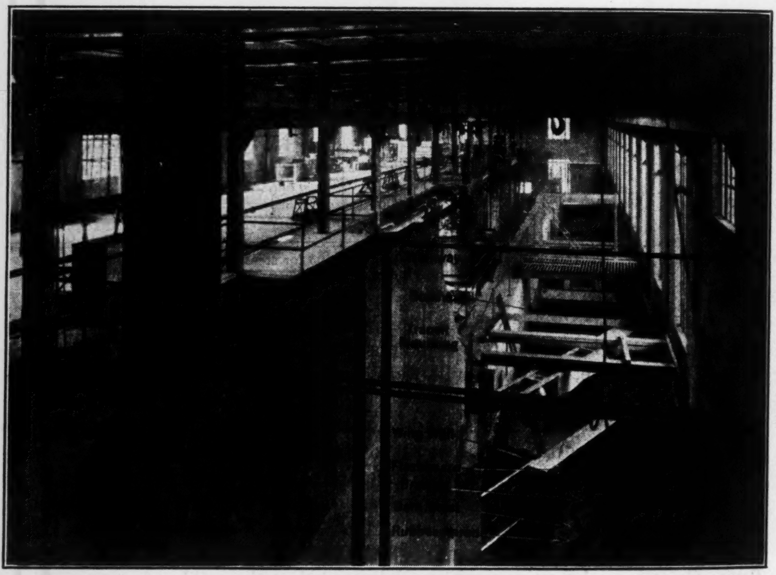

Fig. 2.—Hydraulic Laboratory Flume

In these preliminary tests, because the larger pipes were too strong to fail under a static water load produced by a head-water level even with the top of the flash-boards, a fixed wooden bulkhead with its crest 9 ft 4 in. above the flume floor was provided for increasing the head-water level (see Figs. 3, 4 and 5). Dressed lumber (Douglas fir) $2\frac{5}{8}$ in. thick was used for both the bulkhead and flash-boards, and the horizontal joints were made water-tight by 1-in. splines between the boards. The flash-boards tested in Preliminary Series No. 1 had wedge-shaped "V" joints at the ends (see Fig. 3). In Preliminary Series No. 2, the flash-boards were provided with "butt" joints, or square ends, bound with rubber to reduce leakage as shown in Fig. 4. A rubber apron on the up-stream face of the bulkhead prevented water from discharging over the top of the flash-boards as they deflected during the test.

FINAL SERIES

FIG. 3.—GENERAL LAYOUT; FLUME, TANK, BAFFLES, AND FLASH-BOARDS (NOT TO SCALE)

For the final series of tests the fixed bulkhead was removed, and a one-piece flash-board 16 ft long and of heights varying from 1 ft 10 in. to 5 ft 2 in. above the dam crest was constructed. It was supported by only two pipes, symmetrically placed. The ends, bound with rubber, were closely fitted to wooden wing walls, as shown in Fig. 6. The rubber binding produced no appreciable friction on the end walls, and the flash-board could be moved very freely by hand before the test. One flash-board was balanced horizontally, and the distance of its center of gravity from the bottom was determined. This was used as a basis for computing the center of gravity of the other flash-boards. The lower part of the gate was braced, as can be seen in Fig. 2, to reduce the end deflections caused by water pressure.

The various pipes tested were fitted into the 4-in. sockets in the crest by means of pipe sleeves of various diameters, 20 in. long, the sleeves being machined when necessary to make them nest together properly. The dimensions for nesting pipes and sleeves are given in Table 1 and the sleeves are shown in Fig. 7.

The external diameters of the test pipes were measured in three places: The bottom, top, and at the top of the supporting sockets. The pipes were weighed so that the average internal diameters could be computed. For pipes larger than 2 in., the internal diameter was also measured directly. Computed from the weight, they showed an average variation from directly measured values of 0.3% for the mechanical-test specimens and 0.1% for the eight hydraulic-test specimens compared. The pipes were set up in the sockets and brought to a firm contact with the flash-boards by wooden shims when necessary.

Measuring Devices Used.—A scale, curved approximately to the arc of a circle, with the free length of the pipe as a radius, was fastened either on the top of the flash-board or to the pipe supporting the flash-boards (see Fig. 6). A transit mounted on top of the flume was used to read the scale as the pipe deflected. For later overflow tests, the pipe was extended up through the water to carry the scale (see Fig. 8). As a result of this there could be only a slight degree of vacuum under the nappe.

Up stream from the center of the dam, as shown in Fig. 3, a brass piezometer connection, with an opening $\frac{5}{8}$ in. in diameter, was placed in the floor of the flume and led to a glass-column gage having an internal diameter of 1 in. A similar provision was made for reading the tail-water elevation but this was not used, owing to excessive turbulence in the water below the dam. For the overflow tests with large quantities of water, in which the head-water was also greatly disturbed, a plumb-bob or point gage was used as indicated in Fig. 3. A staff gage, graduated in 3-in. intervals, was painted on the steel bulkhead slot in the flume up stream from the dam for approximate observation of the head-water elevations.

Non-Overflow Tests.—The head-water was raised gradually by means of the pumps, and deflection readings were taken at 3-in. intervals, as determined by the staff gage. Readings of the deflection, staff gage, and glass gage were taken simultaneously on signal. When the pipe began to deflect more rapidly, the readings were taken as the flash-board passed given deflection angles. When

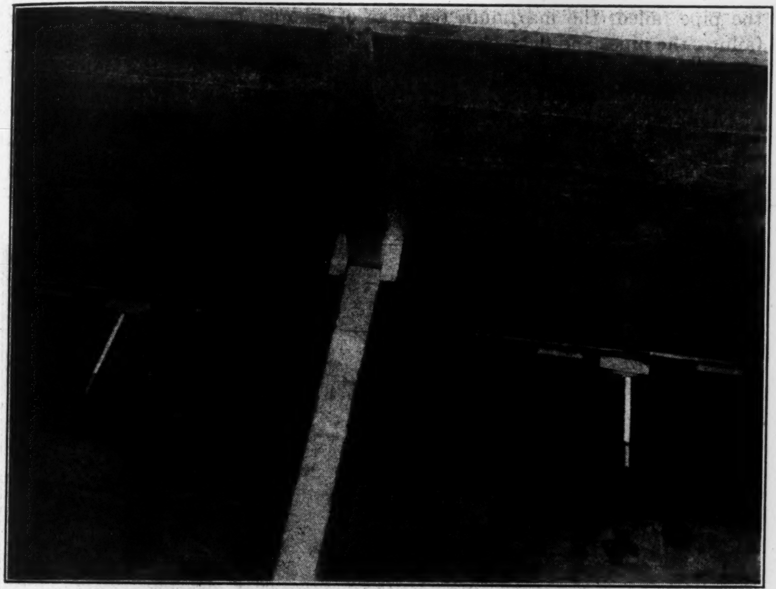

FIG. 4.—FLASH-BOARD PANELS WITH BUTT JOINTS

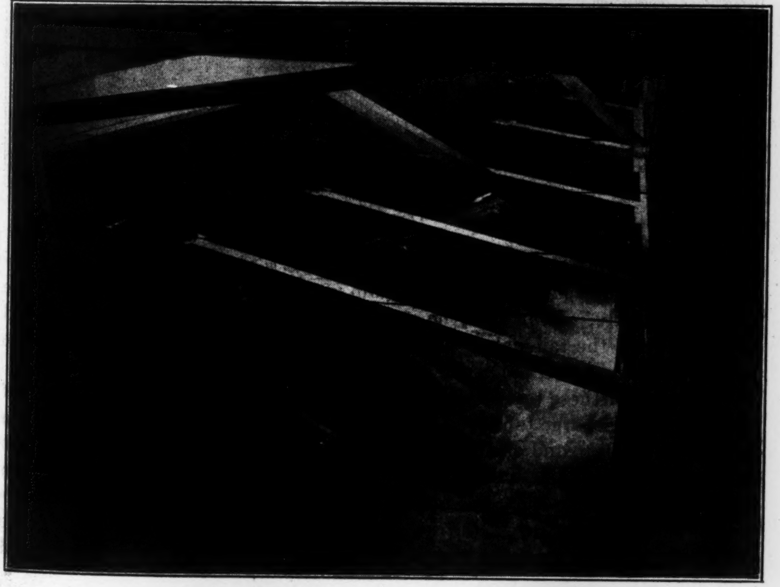

FIG. 5.—FLASH-BOARDS WITH "V" JOINTS AT FAILURE

the pipe failed, the maximum readings of all quantities were taken. After failure, the pipes and flash-boards were examined and photographed. In some of the preliminary tests the flash-boards did not fail because the water flowed over the top of the bulkhead before creating sufficient head for failure. A view of Non-overflow Test No. 4, Preliminary Series No. 1, is shown in Fig. 5.

Overflow Tests.—The same long, single flash-board that was used for the non-overflow tests was used for these tests, and the pipes were also set up in the same manner. However, it was necessary to use a quite different experimental procedure in the overflow tests, because the tail-water rose so rapidly that it backed up against the down stream face of the flash-boards unless failure occurred quickly. Even after the obstruction down stream from the dam had been removed, the tail-water occasionally rose until its surface was above the level of the dam crest, particularly in tests of the higher flash-boards.

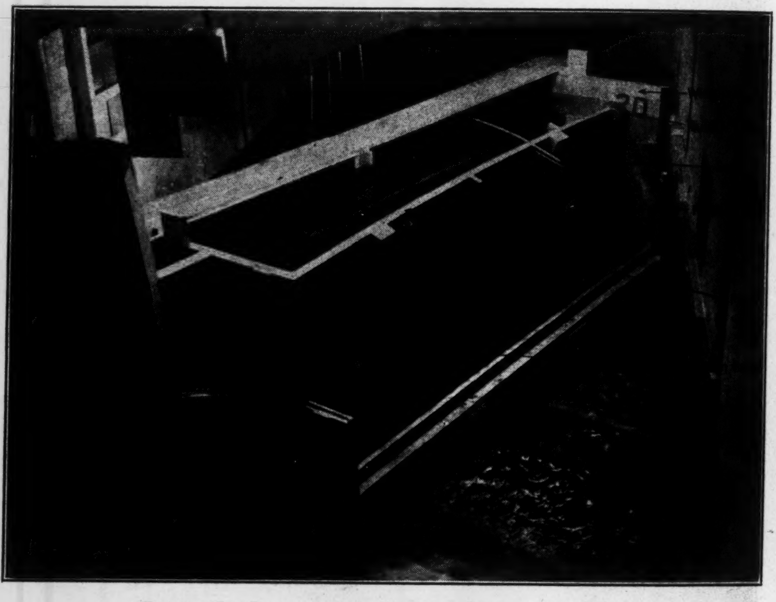

FIG. 6.—NON-OVERFLOW TEST NO. 20 AT FAILURE; 3-INCH PIPE

For some of these tests 35 cu ft per sec was not sufficient, and a method of utilizing the discharge tank was devised. The tank (see Fig. 3) was filled to a point near the top, and one 6-ft gate was opened slightly until the water began to flow over the baffle-bulkhead up stream from the flash-boards. As soon as the water appeared on the face of the flash-boards, simultaneous readings were made and were repeated at every additional 3-in. height. When the water reached the top of the boards, the gate in the discharge tank was opened rapidly, and the head of the water flowing over the boards was brought quickly to the maximum that could be obtained. In this manner a large discharge was produced over the flash-boards—at times probably as much as 150 cu ft per sec. The deflection was observed closely and, at the instant of failure, readings were taken of all quantities. The failure was fairly clear-cut, in that the movement of the pipe accelerated gradually until a sudden collapse occurred. A view of Final-Series Overflow Test No. 27 at the point of failure is shown in Fig. 8. If the tail-water rose above the dam crest level (base of flash-board) before failure of the flash-board pipes, the flume was drained and the test repeated.

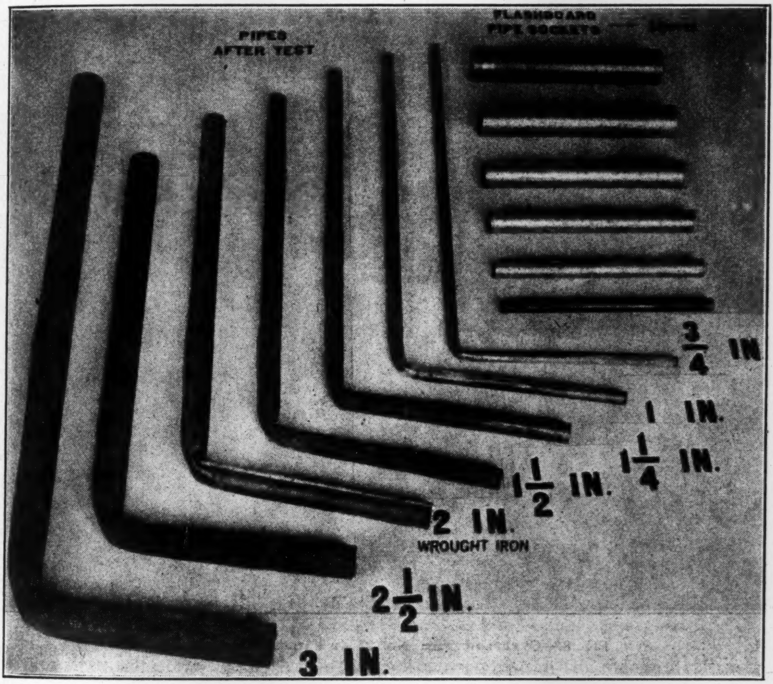

Fig. 7.—Pipes and Pipe Sleeves after Tests

Fig. 7 shows the typical appearance of the pipes after failure. The bending was concentrated at the section of the pipe in the plane at the top of the socket: All of the pipes collapsed at this section, most of them splitting along the seam, and some across the bend.

Accuracy of Measurement.—For most of the tests the head was determined by means of the glass-column gages, but in the later overflow tests the point gage was used. By comparative tests it was established that the head measurement was accurate to 0.01 ft for the non-overflow tests, 0.02 ft for most of the overflow tests, and 0.03 ft for tests with violent disturbance of the head-water.

Results of Hydraulic Tests.—The net result of the Preliminary Series No. 1 was to disclose that the indeterminate influence of the binding of the "V" joints was frequently as great as the supporting power of the pipe, and therefore such joints could not be tolerated. Preliminary Series No. 2 also showed sufficient binding in the 90° "butt" joints to interfere with the design of the flash-boards on a short spillway, although the effect would probably be insignificant on a long spillway. In both series the stresses in the pipes computed from the water loads were excessive.

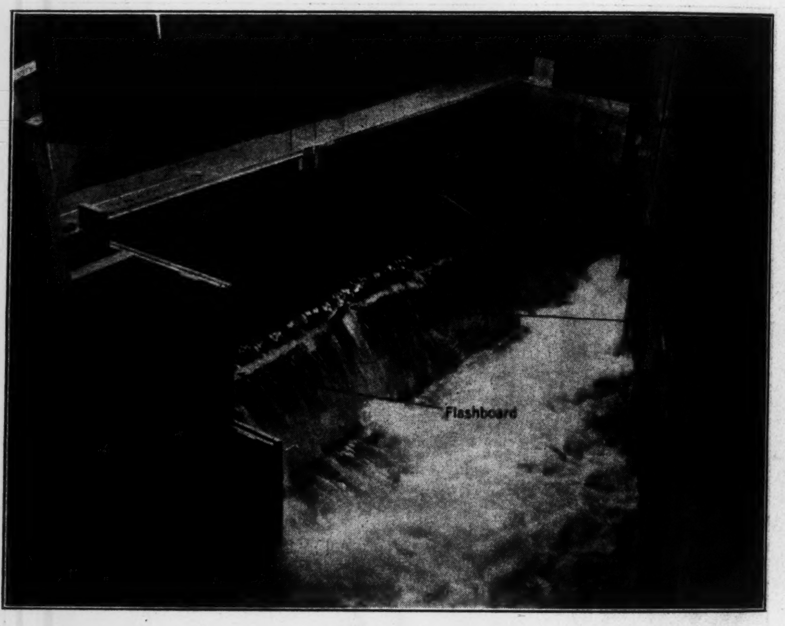

FIG. 8.—OVERFLOW TEST NO. 27 AT FAILURE; 1½-INCH PIPE

Accordingly, cognizance is given only to the results of the final series of tests, where end slots were eliminated, leaving free movement at the ends of the flash-boards along vertical walls at right angles to the center line of the gate. Notwithstanding turbulence, a possible slight degree of vacuum under the nappe, and varying rates of application of pressure, the steel pipe collapsed within sufficiently narrow limits to justify confidence that its behavior can be depended upon. The characteristic of uniform bending up to a critical yield angle from the vertical of from 20° to 30°, followed by a rapid collapse thereafter, is favorable for automatic flash-board control. Results based on this series are analyzed, together with those of the mechanical tests, under the heading "Results of Experiments."

Mechanical Tests

Duplicate specimens 36 in. long were cut from the pipes used for the hydraulic tests and were used for mechanical tests. The specimens varied from $\frac{3}{4}$ in. to 3 in. in size. One specimen of wrought-iron pipe was tested also. The internal diameters were computed in the same manner as for the hydraulic tests; that is, from the weight and external dimensions.

The tests were made in a hydraulic testing machine of 100 000-lb capacity. As shown in Fig. 9, each pipe was loaded as a cantilever beam. The assembly of pipe sleeves used in the hydraulic tests was used also in the mechanical tests to simulate the same conditions of support. The load was applied to the pipe 10 in. from the support through a steel plate corresponding to the actual flash-board loading. During each test the load was applied in increments of approximately 200 lb, and the deflection of the end of the pipe for each load was computed from the readings of two dial gages. After the yield point of the pipe was passed and the pipe deflected excessively, the dial gages were removed, and the vertical distance from the pipe to the platen of the machine was measured until the maximum load was reached.

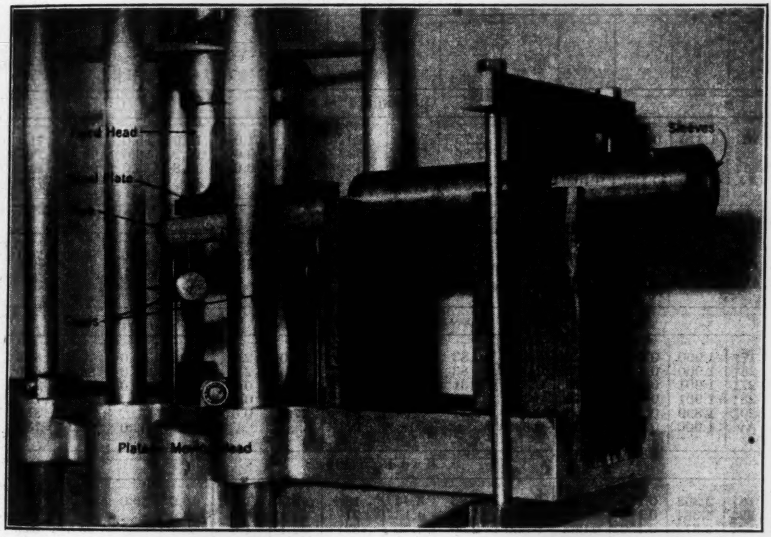

FIG. 9.—MECHANICAL TEST NO. 7, $1\frac{1}{2}$-INCH PIPE—PLATEN, GAGES, AND SLEEVES

RESULTS OF EXPERIMENTS

General.—In arriving at the principal objective—the modulus of rupture and design of flash-board supports—the data from the tests were analyzed in the

following order:

(1) The actual bending moment on the pipe and the corresponding stress were computed as accurately as possible throughout the range of the test;

(2) Values of the modulus of rupture and the yield point for each pipe were determined for both the hydraulic and the mechanical tests;

(3) Values of the modulus of rupture determined for the hydraulic tests in Item (2) were used for the computation of the bending moment at which the pipe should fail; then, on this basis, formulas of various degrees of precision were set up for determining the corresponding water head;

(4) Simplified formulas for use in practical design were developed (moduli of rupture for use with these formulas were obtained by application of the formulas to the laboratory test heads);

(5) Using the values of modulus of rupture from Item (4) a simplified formula for standard sizes of pipe was set up for the prediction of the water head at failure;

(6) The laboratory set-up was assumed to represent a field installation. (The various design formulas, together with their appropriate value of modulus of rupture, were applied thereto and the resulting design head for failure was determined. These values were compared with the observed heads and the relative precision of the formulas determined);

(7) The simple method of design from Item (5) was applied to field structures and check tests were obtained; and,

(8) The original test data referring to Items (1), (2), and (4) are summarized in Table 2. Values in Column (14) are found by Equations (19*b*) or (20) (presented subsequently), divided by the section modulus for standard steel pipe given in Column (5), Table 3. The moment formulas in Items (3) and (4) are derived and discussed in the section on "Moment Formulas for Design." The heads computed for Item (6) are summarized in Table 3. The application of Items (5) and (7) is discussed in the section on "Design of Pipe Supports." Finally, suitable values of moduli of rupture and bending moment formulas are recommended in the "Conclusions." A summary of the bending moment formulas used in the computation of heads in Table 3 is presented in Table 4, the formulas being derived subsequently herein.

Notation.—The letter symbols in this paper are defined where they first appear and are assembled for convenience of reference in Appendix II. The term "kips," when used in this paper, denotes "kilo-pounds"; that is, thousands of pounds.

Computation of Stress in Pipe.—The cross-section of each pipe was assumed to be circular, and its section modulus was computed according to the standard formula:

$$S = \frac{\pi \, (D_e^4 - D_i^4)}{32 \, D_e} \qquad \text{.....................(1)}$$

in which: S = section modulus (Column (5), Table 2); D_e = external diameter of pipe; and D_i = internal diameter of pipe. The stress in the pipe was then computed from the usual formula

$$f = \frac{M}{S} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which M = bending moment in pipe; and, f = stress at the outer fiber.

Computation of Bending Moment.—Thick planks were used at the bottom of all of the flash-boards, and variations in height were obtained by changing the thin section at the top. Accordingly, the exact relation between the depth of the water and the bending moment produced by the water pressure on this irregularly-shaped flash-board could not be expressed readily in general terms;

3(*a*)	$M = 375\,L\,h^2\left(H_1 + \frac{h}{3}\right)$	(19*b*)	(12)
(*b*) NON-OVERFLOW CONDITIONS			
4	$M = M_B + M_N = M_{B^*} + w\,L\left(\frac{H^3 - 3\,H^2\,t\sin\theta}{6\cos^2\theta}\right)$	(4*b*) and (15)	(21)
5	$M = M_{N'} = w\,L\left(\frac{H^3}{6\cos^2\theta}\right)$	(16)	(22)
6	$M = H_H = \frac{w\,L\,H^3}{6}$	(17)	(23)
6(*a*)	$M = 125\,L\,H^3$	(20)	(24)

* Computed separately.

so it was computed individually for each case. Later, simplifications were made in the assumed loadings, and general expressions for the moment were derived on that basis. A diagram similar to Fig. 10, showing all of the conditions at failure, was made for each test, and the hydraulic-pressure distribution was determined for all parts of the flash-board, assuming static conditions. The effective bending moment, M, on the pipe was computed by taking the moments

FIG. 10.—FLASH-BOARD PRESSURE DIAGRAMS

of all the forces around the base of the board, O. The weight of the flash-board was appreciable in most of the tests, and hence its moment was added to that due to the water pressure. The moments are given in Columns (9) to (11), Table 2. These moments were computed individually for the exact conditions of the test and not from the simplified moment formulas, as was done for Column (14). The stress in the pipe was computed from the moment by the formula

$$M = f\,S \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (3)$$

An example of the computation of bending moment and pipe stress is given in Appendix III for the conditions shown in Fig. 10(a).

The assumption of static conditions obviously is correct as long as there is no water flowing over the flash-boards, and it is nearly correct, even when there is overflow, as long as both the deflection of the flash-board and the depth of overflowing water are small. No pressure measurements were made on the flash-boards, but unpublished tests made by the Pennsylvania Water and Power Company of Baltimore have shown that, as the depth of overflow, or the deflection, was increased, and the water moved up along the face of the board at an appreciable velocity, the actual pressure on the board was less than that due to the static conditions assumed. For the non-overflow tests, however, the assumption of static conditions was practically correct.

Stress-Deflection Curves.—The stresses in the pipe for each of the readings made before failure were computed by the same procedure, and stress-deflection curves were plotted for each test. Typical curves are shown in Fig. 11. The yield point (18) of the pipe for these tests was taken as the approximate stress at which the stress-deflection curve breaks away from its initial straight section. It was desired to determine the stress at which the pipes first began to bend

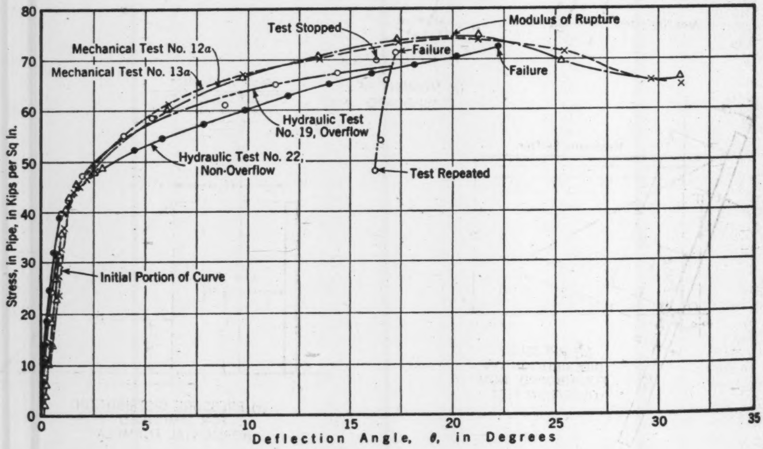

Fig. 11.—Typical Stress-Deflection Curves for a 2½-Inch Pipe

noticeably in these tests, since it was thought that they might possibly fail at the head causing this stress. When the deflection increases there is a considerable increase in the moment of the hydraulic load, even if the head remains constant. For this feature of the investigation, the term "yield point" seemed better adapted than other terms considered, although it does not accord with the standard definition. These values were determined from the curves and are given in Column (12), Table 2.

The stress computed from the maximum moment was called the "modulus of rupture," and these values are given in Columns (13) and (14), Table 2. (The term "modulus of rupture" has been used to indicate the maximum computed flexural strength, based on the original section of the pipe, in accordance with engineering practice.)

The stress-deflection curves for 2½-in. pipe, shown in Fig. 11, were selected as typical of both the hydraulic and mechanical tests. The curves are seen to be generally similar in shape throughout their range but to differ in the value of the modulus of rupture. It may be observed in Fig. 11 that, as the headwater was lowered and again raised for Test No. 19, the corresponding stress-deflection curve tends to be parallel to its initial direction. Furthermore, as would be expected, the curve comes back to its original position before going on to the point at which the pipe failed.

The beginning of the stress-deflection curve, within the limits of error of the test, was observed to be a straight line and served to determine the approximate yield point as already described at about 46 kips per sq in. The deflection of the pipe over the elastic range of the test was very small—that is, less than 2° as compared to that at its subsequent failure at 20° to 30° deflection. Extensive studies of the properties of the pipe within this range of loading failed to yield any results pertinent to the main objective (design of flash-board supports); consequently no further consideration was given to conditions within the elastic range.

The deflection at modulus of rupture was plotted against the corresponding size of pipe for both the hydraulic and mechanical tests, using the data given in Table 2. The average values for the hydraulic tests showed a fairly consistent agreement with the mechanical tests. In both types of tests the deflection at failure is less for the larger pipes than for the smaller ones. A probable explanation of the latter fact is given subsequently herein in connection with the relation of modulus of rupture to pipe size. For the hydraulic tests the deflection ranged from 15° to 30° and the average was taken as 20° for later use in connection with the design of flash-boards.

Yield Point Stress.—The stress at the yield point for all of the pipes tested was found to range from 40 to 55 kips per sq in. averaging 49 kips per sq in. Beyond this stress permanent bending occurred. (It was found later, in field tests, that a value of 46 kips per sq in., computed by the horizontal formula, was more nearly in accordance with the facts; some tests gave as low as 40 kips per sq in.) However, failure did not occur until the pipe had traversed the large deflection angle of 15° to 30°, the angle of failure being consistent for pipes of the same size. Thus, for an actual installation, if the pipes had been bent only slightly by a small flood, they still could be depended upon to fail at the desired head caused by a subsequent larger flood.

The wide spread between the yield point and the modulus of rupture of pipe supports is particularly significant. Instead of beginning decisively to fail at the yield point, the pipe did not actually fail until the stress value approached the modulus of rupture, although it was loaded beyond the yield point for a considerable period.

From these characteristics it is evident that in designing flash-board supports the diameter and spacing of the pipe should be such that the yield point, and resulting permanent bending of the pipe, will not be reached too frequently. The natural tendency is to build flash-boards too close to the maximum permissible water level in order to gain as much head and storage as possible. Then a small flood will bend the pipe, making the gate unsightly, or collapse it, requiring the pipe to be replaced. On the other hand, if the pins are designed for an initial stress of 30 to 50 kips per sq in., as well as for the ultimate modulus of rupture required, premature deformation due to debris, waves, or high water can be largely avoided.

The deviations of the heads at which the pipe should begin to bend, from the heads at which failure actually occurred, are shown in Columns (19) and (31), Table 3. These columns show, furthermore, that if the yield point is used in place of the modulus of rupture to compute the heads at which the pipes should fail, this will lead to values distinctly lower than the actual heads at failure. This comparison was made partly because of the belief (apparently held previously, but now shown not to be the case) that once the yield point of the pipes had been reached, the installation would go on to failure without any further increase in head.

Modulus of Rupture-Pipe Size.—In order to determine the proper modulus of rupture for the design of pipe supports, the relationship of modulus of rupture to pipe size was studied. The values of modulus of rupture given in Columns (13) and (14), Table 2, for both the hydraulic and mechanical tests, were plotted against the corresponding pipe size given in the sub-captions of the table (see Fig. 12). They range from 96 to 61 kips per sq in., and the values of the modulus of rupture, obtained from the hydraulic tests were approximately 20% greater for the smallest pipes than for the largest pipes. The values for the mechanical tests show a similar relationship between extreme sizes, although it is not so marked for the intermediate sizes. This relationship is due mainly to the greater relative wall thickness of the smaller pipes, which is indicated by comparing the values in Column (4), Table 2, with the standard pipe size. It is an accepted fact (19) that, when any structural member is stressed in bending beyond the elastic range, the stress distribution becomes non-linear, and the extreme-fiber stress computed on the assumption of a linear distribution exceeds the actual value. The greater the concentration of the material at the neutral axis, the greater this excess will be. Thus, although the actual stress occurring in the extreme fiber of two pipes may be the same, yet the computed value would be greater for the thicker-walled pipe. The larger pipes, with the relatively thinner walls, fail at smaller deflection angles and yield lower moduli of rupture.

Comparison of Hydraulic and Mechanical Tests.—For the mechanical tests the moments and resulting stresses were computed directly from the measured loads. The yield point for each pipe was determined from stress-deflection curves in the same manner as for the hydraulic tests and the results are given in Column (12), Table 2. Values of modulus of rupture determined from the maximum moment are given in Columns (13) and (14).

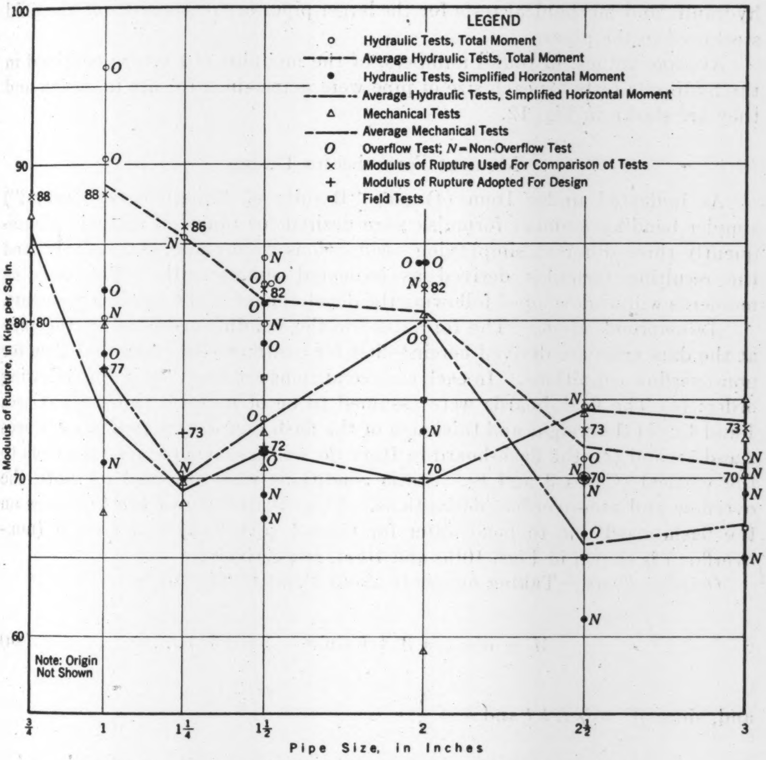

FIG. 12.—RELATION BETWEEN MODULUS OF RUPTURE AND PIPE SIZE

It is believed that the conditions were more nearly determinate, and more nearly in accordance with the assumptions made, in the tests of the 2½-in. and 3-in. pipes than for the smaller pipes. The results obtained in the mechanical tests agree quite well with those obtained in the hydraulic tests for the two largest sizes of pipe tested.

An exhaustive analysis of the discrepancies between the results of the mechanical and the hydraulic tests for pipe diameters of 2 in. and smaller was made (15*a*), but no obvious explanation of the lack of agreement was found. It was concluded that the discrepancy between the hydraulic and mechanical tests is a function of any or all of a number of minor factors, none of which can be evaluated with any certainty. These include: (*a*) Uncertainty as to the portion of the water load that was actually transmitted to the pipes; (*b*) possible uncertainties as to the exact values of the moments applied in the mechanical tests, due to the large deflection at failure; (*c*) uncertainties as to the exact shape and condition of the pipe at the support; and (*d*) insufficient number of pipes tested. The values of modulus of rupture determined by the hydraulic and mechanical tests for the larger pipes are reasonable for the mild steel used in the pipes.

Average values, in round numbers, of the modulus of rupture obtained in the hydraulic tests for each size of pipe were determined for use in design and they are shown in Fig. 12.

Moment Formulas for Design

As indicated under Item (4) (see "Results of Experiments: General") simpler bending moment formulas were desired for practical design. Consequently three different simplifying assumptions were made, successively, and the resulting formulas derived as indicated subsequently. The resisting moments will be developed following the development of the bending moments.

Assumptions Made.—The formulas for the bending moment on the pipe at the dam crest are derived herein—first for overflow conditions and then for non-overflow conditions. In each case conditions are assumed in the following order: (*a*) The flash-boards were assumed to be of uniform thickness (Cases 1 and 4); (*b*) the weight and thickness of the flash-board were neglected (Cases 2 and 5); and (*c*), the flash-board in Item (*b*) was assumed to be swung back to the vertical (Cases 3 and 6). Static conditions were assumed for both the overflow and non-overflow derivations. The distribution of the pressures on the flash-board due to head-water for Case 1 (overflow) and Case 4 (non-overflow) is shown in Figs. 10(*b*) and 10(*c*), respectively.

Overflow Tests.—Taking moments about Point O, Fig. 10(*b*):

$$M = W\,a_w = W\left(\bar{h}\sin\theta - \frac{t}{2}\cos\theta\right) \ldots\ldots\ldots\ldots (4a)$$

and, since $W = \gamma\,L\,h\,t$ and $\bar{h} = \frac{h}{2}$:

$$M_B = \gamma\,L\left(\frac{h^2\,t}{2}\sin\theta - \frac{h\,t^2}{2}\cos\theta\right) \ldots\ldots\ldots\ldots (4b)$$

in which: W is the weight of the flash-board; $\bar{h}$ is the distance from the base of the flash-board to its center of gravity; a_w is the lever arm of the weight W; γ is the specific weight of the timber used for the flash-board (36 lb per cu ft); L is the length of flash-board along the crest supported by one pipe (average spacing of the supporting pipes); and, M_B is the moment due to the weight of the flash-board. The flash-board moment was appreciable only at deflection angles greater than 5 degrees.

Case 1. Normal Moment.—The flash-board is assumed to be of constant thickness t. The trapezoidal pressure diagram is divided into a rectangle and a triangle for convenience, as shown in Fig. 10(c). Consequently, the moment of the water pressure normal to the flash-board is:

$$M_N = P_1\, a_1 + P_2\, a_2 + P_3\, a_3 \dotfill (5)$$

in which $a_1 = \frac{h}{2}$; $a_2 = \frac{h}{3}$; $a_3 = \frac{t}{2}$; and,

$$P_1 = w\, L\, h\, (H - t \sin\theta - h \cos\theta) \dotfill (6a)$$

$$P_2 = \frac{w\, L\, h}{2}\, (h \cos\theta) \dotfill (6b)$$

$$P_3 = w\, L\, t\, H \left(\text{neglecting } \frac{t}{2} \sin\theta\right) \dotfill (6c)$$

in which w is the specific weight of water (62.4 lb per cu ft). Hence:

$$M_N = w\, L\, h\, (H - t \sin\theta - h \cos\theta)\, \frac{h}{2} + \frac{w\, L\, h}{2}\, (h \cos\theta)\, \frac{h}{3} + w\, L\, t\, H\, \frac{t}{2} \dotfill (7a)$$

or

$$M_N = w\, L \left(\frac{H\, h^2}{2} - \frac{t\, h^2 \sin\theta}{2} - \frac{h^3}{2} \cos\theta + \frac{h^3}{6} \cos\theta + \frac{H\, t^2}{2}\right) \dotfill (7b)$$

The term containing t^2, in Equation (7b), can be neglected in comparison with the other terms; and thus, the normal-moment formula becomes

$$M_N = w\, L\, h^2 \left(\frac{H}{2} - \frac{h \cos\theta}{3} - \frac{t \sin\theta}{2}\right) \dotfill (8)$$

Case 2. Normal Moment Neglecting Weight and Thickness of Flash-Board.—Making $t = 0$ in Equation (8), the normal moment, neglecting the weight and thickness of the flash-board, is:

$$M_N' = w\, L\, h^2 \left(\frac{H}{2} - \frac{h \cos\theta}{3}\right) \dotfill (9)$$

Case 3. Normal Moment Considering Flash-Board Swung Back to the Vertical, and Neglecting Weight and Thickness of Flash-Board.—In Equation (9), make $\theta = 0$, and the normal moment (considering the flash-board to be swung back to the vertical, and neglecting the weight and thickness of the flash-board) becomes:

$$M_N'' = M_H = w\, L\, h^2 \left(\frac{H}{2} - \frac{h}{3}\right) \dotfill (10)$$

which is the horizontal moment formula.

Non-Overflow Tests.—The moment of the flash-board itself is the same as before (Equation (4b)).

Case 4. Normal Moment.—In Fig. 10(d) the moments are taken around Point O as in Equations (4):

$$M_N = P_1\, a_1 + P_3\, a_3 \dotfill (11)$$

in which $a_1 = \frac{y}{3}$; $a_3 = \frac{t}{2}$; y = slant height, wetted surface of flash-board; and,

$$P_1 = \frac{w\,L\,y\,(H - t\sin\theta)}{2} \qquad (12a)$$

$$P_3 = w\,L\,t\,H \qquad (12b)$$

$$M_N = w\,L\,y\,\frac{(H - t\sin\theta)}{2} \times \frac{y}{3} + w\,L\,t\,\frac{H\,t}{2} \qquad (12c)$$

Since

$$y = \frac{H - t\sin\theta}{\cos\theta} \qquad (13)$$

Therefore,

$$M_N = w\,L\left[\frac{(H - t\sin\theta)^3}{6\cos^2\theta} + \frac{t^2\,H}{2}\right] \qquad (14)$$

In Equation (14), expand $(H - t\sin\theta)^3$ and neglect terms containing t^2 and t^3; and the normal-moment formula is found to be:

$$M_N = w\,L\left(\frac{H^3 - 3\,H^2\,t\sin\theta}{6\cos^2\theta}\right) \qquad (15)$$

Case 5. Normal Moment Neglecting Weight and Thickness of Flash-Board.—If $t = 0$ in Equation (15), the normal moment, neglecting the weight and thickness of the flash-board, becomes:

$$M_N' = w\,L\left(\frac{H^3}{6\cos^2\theta}\right) \qquad (16)$$

Case 6. Normal Moment Considering Flash-Board Swung Back to the Vertical, Neglecting Weight and Thickness.—Considering the flash-board swung back to the vertical and neglecting weight and thickness, $\theta = 0$ and $t = 0$, from which, by Equation (15), the horizontal-moment formula becomes:

$$M_N'' = M_H = \frac{w\,L\,H^3}{6} \qquad (17)$$

Case 3(a) Simplified Horizontal Moment Formula.—Since it was found that compensating refinements, such as weight and thickness of flash-boards, angle of deflection, and increase of normal moment over horizontal moment, had no practical effect in the tests, the horizontal moment has been adopted as a working basis for design (see Item (7), heading "Results of Experiments: General"). The formulas were simplified for field and office use as follows (see Fig. 10(*e*)).

Overflow Tests.—In Equation (10), written in the form,

$$M_H = w\,L\left(\frac{H\,h^2}{2} - \frac{h^3}{3}\right) = M \qquad (18)$$

substitute w = 62.4 lb per cu ft and $H_1 + h = H$, in which H_1 is the head of water, in feet, above the top of the flash-board. Then, the moment, in foot-pounds, is

$$M = 62.4\,L\left(\frac{H_1\,h^2}{2} + \frac{h^3}{6}\right)\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(19a)$$

or, in inch-pounds,

$$M = 375\,L\,h^2\left(H_1 + \frac{h}{3}\right)\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(19b)$$

Non-Overflow Tests.—From Equation (17), the moment, in inch-pounds, is

$$M = 125\,L\,H^3\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(20)$$

Comparison of Computed with Measured Heads at Failure.—As indicated under Items (5), (6), and (7) (heading, "Results of Experiments: General"), the next step in the investigation was to compare the heads at which flash-board installations should fail, as computed by the various bending moment formulas (Table 4), with the heads at which failure actually had been observed to occur on installations. The laboratory installations used in this investigation to determine the modulus of rupture obviously afforded a convenient opportunity to make such a comparison. The flash-boards were assumed to be supported by standard steel pipe having the dimensions and section moduli given in Table 3. The moduli of rupture used were selected from Fig. 12 and are given in Column (6) of Table 3. For each size of pipe used, the two quantities, S and f, determined the resisting moment to be used in design. No allowance was made for any partial vacuum under the sheet of water flowing over the flash-boards, since they were ventilated at each end.

It should be noted carefully that this is really a comparison of the relative accuracy with which various approximate formulas, nominal pipe sizes, and moduli of rupture will determine the head at failure of a flash-board installation, as compared to the actual head at which failure occurred. The discrepancies found might be somewhat larger when comparisons are made with other installations.

The data for standard pipe, the dimensions of the flash-boards, and spacing of pipe were substituted in the bending moment formulas (Table 4) and the head at which the flash-board should fail was determined (Table 3).

The heads at which the pipes should begin to bend were computed for the horizontal formula using a stress of 46 kips per sq in. to determine the bending moment. The resulting heads are given in Columns (18) and (30) of Table 3. The heads at which pipe should fail are given in Columns (12) and (24); and, the heads at which failure actually occurred are given in Columns (13) and (25).

The differences between the computed heads and the measured heads are given in Columns (14) to (17) and (26) to (29). The values obtained from the normal-moment formula, including the moment due to the flash-board (Cases 1 and 4), and similar values neglecting the flash-board moment (Cases 2 and 3), are seen to be very nearly the same for both the overflow and the non-overflow tests. The average difference ranges from 2% high to 1% low, with a maximum variation from + 5 to − 3 per cent.

The more approximate and convenient simplified horizontal moment formulas, neglecting both the flash-board moment and the angular deflection

(Cases 3*a* and 6*a*), yielded results within an average of 3% lower than the test heads for the overflow and 2% higher for non-overflow tests. For this formula, values of modulus of rupture developed in the following section and given in Column (7), Table 3, were used. It is seen that the more accurate and complicated formula for normal moment, allowing for both the weight and thickness of the flash-board, probably does not improve the results sufficiently to justify its use. Therefore, Equation (20) for non-overflow tests, and Equation (19*b*) for overflow tests, are recommended for use in the selection of pipe for flash-board supports.

Modulus of Rupture.—In order to determine suitable values of modulus of rupture for design with Equations (19) and (20), values of the test data from Table 2 were first substituted in the formulas and the modulus of rupture computed. They are given in Column (14), Table 2. In Fig. 12, they are seen to be in very close agreement with those of the mechanical tests. Average values of the modulus of rupture in round numbers, to be used in Equations (19) and (20) for flash-board design, were selected for each pipe size.

DESIGN OF PIPE SUPPORTS

The use of the derived formulas Equations (19*b*) and (20), in combination with the relation $M = f\,S$ for the design of the flash-board pipes, can be reduced to a very simple procedure. Since the variables involved are the height of the water above the spillway, height of flash-board, and span between supports, it is customary to designate two of these and solve for a third. Usually the size of pipe is to be determined. If so, and the water level is fixed, it may be necessary to modify the pipe spacing by trial to compensate for the gap between standard pipe sizes. On the other hand, if the pipe size and spacing are fixed, a definite solution for the head results.

Variable Modulus of Rupture.—The maximum bending moment, being a function of the known section modulus of the pipe (computed from standard dimensions) and of the experimentally-determined modulus of rupture, is determined by the latter. This characteristic, as opposed to the expected constant modulus of rupture for a given material, such as steel, constitutes an outstanding feature of the tests. It means that for accuracy, different values of modulus of rupture must be used in determining the maximum bending moment for different sizes of pipe since the modulus of rupture ranges from approximately 70 kips per sq in. for 3-in. pipe to 90 kips per sq in. for ¾-in. pipe (see Fig. 12). It is here that the test results are most valuable, inasmuch as the range in modulus of rupture is by far the greatest variable in the design. Therefore, for reasonable accuracy in the control of head-water elevations, it is preferable to use the tabulated modulus of rupture that corresponds most nearly to the selected pipe size, rather than to assume an average value for all sizes of pipe. As already indicated, if pipe sizes larger than 3 in. are to be used, it is presumed that they will first be checked by additional tests.

Height of Flash-Board.—It is obvious from Equations (19) and (20) that the ratio of the height of the flash-board to the total head of water is important. For the same pipe and spacing, the higher flash-boards fail earlier or under less head of water than do lower boards. To express it another way, for a given height of water above a spillway crest, a high flash-board gate with only a few inches of water flowing over it will fall, whereas a lower flash-board (supported by the same pipe system), overtopped by several feet of water depth, will stand erect. This inherent characteristic must be considered in selecting the appropriate flash-board dimensions for a structure.

Hinges.—If a flash-board gate is hinged at the bottom, the hinges must be loosely fitted. Any binding at the hinge would prevent the flash-board either from swinging freely under water pressure or from transferring its load properly to the pipe support. In either case the load on the pipe would be reduced and it would fail at a higher head than designed.

Typical Design Procedure.—To illustrate design procedure assume a spillway channel 35 ft wide by 8 ft deep, the entire capacity (depth) of which is required in time of flood. It is desired to raise the normal lake level 3 ft (h) above the spillway-level (crest), limit the maximum flood height above this normal water level to 2 ft (H_1), and, at the same time, retain a 3-ft free-board between the maximum flood height and the top of the dam. The cost of widening this spillway channel, so that it would have the same flood capacity at a 5-ft depth, compared to this 8-ft depth, would be prohibitive. The procedure follows:

(1) Pipe spacing: The customary spacing for the supporting pipe for a gate of this height is from 3 to 5 ft since wider spacing requires a gate that is too ponderous to lift back into position after failure, and closer spacing multiplies pipe replacement units. Try eight pipe supports. Then the length supported by one pipe is $\frac{35}{8} = 4.4$. However, since the gate is sufficiently rigid to distribute the loading equally to all the pipe, they act as a whole and are best designed on a basis of total moment. To prevent "curling" at the ends, place a pipe 1 ft from each end of the gate and space the remaining six pipes symmetrically with respect to the center line of the channel.

(2) Determine pipe sizes: Use the overflow formula (Equation (19*b*)) for bending moment, with $L = 35$ ft. Then $M = 375 \times 35 \times 9\,(2 + \frac{3}{3}) = 354\,000$ in-lb. The section modulus $S = \dfrac{M}{f}$ with $f = 70\,000$ lb per sq in. (approximately) yields: $S = \dfrac{354\,000}{8 \times 70\,000} = 0.632$ which indicates pipe between 2-in. and $2\frac{1}{2}$-in. in diameter. By trial it is found that a $1\frac{1}{2}$-in. pipe at each end, with four 2-in. and two $2\frac{1}{2}$-in. pipes alternated symmetrically between, gives a resisting moment of 353 000 in-lb. This is within the working limits.

(3) Check of yield point: Substituting again the combined section moduli of these eight pipes in $M = Sf$ when $f = 46\,000$ lb per sq in. (yield point) yields: $M = 5\,040 \times 46\,000 = 232\,000$, which is equivalent to a head over the gate (Equation (19*b*)) of $H_1 = \dfrac{232\,000}{375 \times 35 \times 9} - \dfrac{3}{3} = 0.9$ ft. If it is probable that a head of 0.9 ft over the gate will occur frequently it would be better either to lower the gate height or use stronger pipe. This encroaches on the free-board during occasional flood peaks, but avoids frequent unsightly bending of the pipe.

INSTALLATION AT SHERANDO LAKE TESTED

An automatic flash-board gate 35 ft long by 3.2 ft high, designed in accordance with the findings of the Hydraulic Laboratory tests, was installed at Sherando Lake, 10 miles south of Waynesboro, Va., in the George Washington National Forest in the fall of 1935 (see Fig. 1). The wooden gate is hinged at eight points and is sufficiently rigid so that the hydraulic load is apparently equal on all of the eight supporting pipes. These pipes are spaced on about 5-ft centers with end pipes about 1 ft from the channel side-walls. The average length of gate supported by one pipe is 4.4 ft. The hinges are placed behind the pipes and are very loosely fitted to avoid binding or taking part of the pipe load.

Floods collapsed the gate three times during 1936. First, on March 20, when the lake level reached a head of 2.42 ft (determined by an automatic gage) over the top of the flash-board, or within 0.12 ft of that specified, the gate opened gently downward with an accelerating speed as it fell into the surging tail-water which cushioned its fall. At first the gate leaned more and more out of plumb until the angle was about 20°; then all pipes collapsed and fell simultaneously.

Following this successful field test of 1-in. pipe, the pipe size was increased progressively, using first $1\frac{1}{2}$-in. pipe and then 2 in. with $1\frac{1}{4}$-in. end pipes. In each case the gate fell when the water surface was 0.1 to 0.3 ft below the designed height—that is, on the safe side. This procedure of first testing a pipe size smaller than the design calls for is recommended where the pipe cost is negligible. This helps to ascertain the effect of local conditions—such as wind, wave and current action, ice thrust, presence of logs and debris, vibration, and partial vacuum under the gate.

Other Installations.—One gate costing $500 saved a spillway cost of $15 000. This particular gate was 30 ft long and consisted of two superimposed vertical sections, the upper 2 ft being designed to fail under a 1.5-ft head and the lower $4\frac{1}{2}$-ft section failing under 3-ft head. Vacuum under the nappe caused this gate to fall at about 7% lower head than would be the case with ventilated overflow.

Checks made on the operation of a number of installed flash-board gates indicate adherence to within about 5% of the design water heads, and in all cases the failure of the gate has been on the safe side.

It has been observed that, in installations where a considerable degree of vacuum is formed beneath the nappe, the gate fails under a lower head-water than otherwise. This offers the alternative of using heavier pipe supports or of breaking the vacuum by vent pipes or by other expedients. However, like all other field test results obtained by following this design method, this vacuum effect tends to lower the maximum flood stage behind the dam.

CONCLUSIONS

The following conclusions have been amplified to include some minor, as well as the major, results of the experiments and field tests because of the dearth of published information on flash-board installations.

(1) Flash-boards with standard, steel-pipe supports can be designed to fall consistently within narrow limits under specified conditions.

(2) In the design of pipe supports for flash-boards, the simplified horizontal moment formula (Equations (19*b*)) for ventilated overflow conditions, and Equation (20) for non-overflow conditions, will give results within practical limits (approximately 3 per cent). Stock commercial steel pipe can be used, the section modulus being computed from internal and external diameters taken from lists of pipe standards as shown in Table 2. The moduli of rupture and resulting bending moments recommended for use in these formulas are given in Table 5. The stress at the yield point may be taken as 46 000 lb per sq in.

TABLE 5.—RECOMMENDED VALUES, MODULI OF RUPTURE AND RESULTING BENDING MOMENTS

Description	Pipe Sizes (Nominal Diameter) in Inches						
	¾	1	1¼	1½	2	2½	3
Modulus of rupture, in pounds per square inch	80 000	77 000	73 000	72 000	70 000	70 000	70 000
Bending Moment, in inch-pounds	5 600	10 400	17 150	23 800	39 200	74 900	122 500

(3) If greater accuracy is desired, the appropriate normal-moment formulas (Equations (4), (8) or (15)), may be used with the moduli of rupture shown in Column (6), Table 3.

(4) The modulus of rupture to be used in design may be determined experimentally from mechanical as well as hydraulic tests for pipes larger than 1 in. in diameter.

(5) The ratio of height of flash-board to total head of water should be such that ordinary floods can be passed without permanent bending of the pipe supports. In other words, the yield point of the pipe must be taken into consideration in design.

(6) Any unusual local conditions must be considered in the application of the formulas.

(7) The load on flash-board pipes may be reduced and increased successively without producing failure, as long as the maximum load at which failure should occur is not reached. When the maximum load (head) is reached, however, the pipe will assuredly collapse and fall completely.

(8) Uniform bending up to a critical angle with the vertical, of from 20° to 30°, usually precedes failure.

(9) Vacuum under the nappe causes vibration and collapse of the flash-board pipes at lower heads than designed. This is generally on the safe side.

(10) Because of loading conditions and relative wall thickness, the modulus of rupture used in designing steel pipes for flash-board supports is considerably greater than the minimum specified ultimate tensile strength of the metal in the pipe. This variation is greater for the smaller pipes.

(11) The formulas recommended for design (see Table 4) do not allow for the indeterminate binding effect of wedge, or "V"-jointed, flash-boards, or the

interlocking and wedging of "butt"-jointed flash-boards, in preventing failure at the desired elevation of the head-water.

(12) The use of solid steel or iron pins for flash-board supports seems to be not as dependable as the use of standard steel pipe.

ACKNOWLEDGMENTS

The success of the work was due largely to co-operation between the U. S. Forest Service and the National Bureau of Standards.

All hydraulic tests were conducted in the Hydraulic Laboratory Section of the latter under the general supervision of H. N. Eaton, Chief of the Section. Mr. Eaton also carefully reviewed and edited the previous report as well as the manuscript of this paper. The apparatus was constructed by C. W. Elliot of the laboratory staff, and in making observations, other members of the staff, as well as men from the office of the Forest Service, participated. The mechanical tests were made in the Engineering Mechanics Section by A. H. Stang, and others, under the supervision of H. L. Whittemore, Chief of the Section. The work of these laboratories is supervised generally by H. L. Dryden under L. J. Briggs, Director of the National Bureau of Standards.

J. C. Dort, M. Am. Soc. C. E., proposed the laboratory experiments to check the design for the installation of flash-boards at Sherando Lake. F. L. Brown, Jun. Am. Soc. C. E., was assigned to the hydraulic laboratory during the tests and A. H. Ronka, Assoc. M. Am. Soc. C. E., assisted in the analysis of results.

Regional Forester, R. M. Evans, is Chief of Region 7, U. S. Forest Service. T. W. Norcross, M. Am. Soc. C. E., is Chief of the Division of Engineering, U. S. Forest Service, and F. A. Silcox is Chief of the Forest Service.

The Pennsylvania Water and Power Company of Baltimore loaned their voluminous test data freely and facilitated inspection of their flash-board installations.

APPENDIX II

NOTATION

The following notation conforms essentially with American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials,[5] compiled by a committee of the American Standards Association with Society representation, and approved by the Association in 1932:

a = lever arm to a local force, P; a_1 = lever arm to P_1; a_2 = lever arm to P_2; a_3 = lever arm to P_3; and a_w = lever arm to the force W;

D = diameter of pipe; D_e = external diameter; and, D_i = interior diameter;

f = stress in the outer fiber of a pipe;

H = height of head-water above the crest of the dam at failure; H_1 = height of water surface above the top of the flash-board;

h = height of the flash-board above the base of the hinge; $\bar{h}$ = distance from the base of the flash-board to its center of gravity;

---

[5] A. S. A.—Z10a—1932.

L = length of flash-board, along the crest, that is supported by one pipe; average spacing of the supporting pipes;

M = maximum bending moment; M_B = the moment due to the weight of the flash-board; M_N = moment due to water pressure normal to the flash-board; the total moment acting on a supporting pipe is $M_N + M_B$; M_N' and M_N'' = the approximate moment due to water pressure on the flash-board; M_H = the moment due to water pressure on a flash-board assumed to be swung back to the vertical position—that is, the "horizontal moment";

P = concentrated loads; P_1, P_2, etc. are local forces;

S = section modulus;

t = average thickness of the flash-board;

W = weight of flash-board, in pounds per pipe;

w = specific weight of water (62.4 lb per cu ft);

y = slant height, wetted surface of flash-board;

γ = specific weight of the timber used for flash-boards;

θ = angular deflection of the flash-board from the vertical.

APPENDIX III

Computation of Moment and Stress

Overflow Test No. 32.—The pressure diagram for Test No. 32 is shown in Fig. 10 (a) and the pipe data are given in Table 2. The distribution of water pressure on the flash-boards is shown diagrammatically, and the force diagram thus obtained is divided into convenient areas for computing the moment. All dimensions are in feet. The summation of the moments of all the areas around the base at Point O represents the total water moment. The moment of W about Point O is the flash-board moment.

Referring to Fig. 10 (a): $H = 4.15$ ft; $W = 150$ lb; $\bar{h} = 1.17$ ft; $\theta = 21°$; $M = M_B + M_N$; and,

$$M_B = W\,(\bar{h} \sin \theta - 0.11 \cos \theta) \ldots\ldots (21)$$

Substituting appropriate values in Equation (21), $M_B = 540$ in-lb.

For normal moment take moments around Point O:

$$M_N = P_1\,(2.18) + P_2\,(2.07) + P_3\,(0.93) + P_4\,(0.62) + P_5\,(0.11) - P_6\,(0.18) \ldots (22)$$

Again, substituting appropriate values in Equation (22), $M_N = +\,7.96\,(12\,w\,L)$ in-lb; and, neglecting P_6, $M_N = 48\,130$ in-lb. Then, $M = M_B + M_N = 500 + 48\,100 = 48\,600$ in-lb.

The stress in the pipe (modulus of rupture) $f = \frac{M}{S} = \frac{48\,600}{0.616} = 78\,900$ lb per sq in. as shown in Column (13), Table 2.

DISCUSSION

William P. Creager,[6] **M. Am. Soc. C. E.** (by letter).—An excellent series of experiments, indicating the strength of flash-board pins, has been presented in this paper. It should be noted that all of the experiments were made with a completely aerated jet yet, in most cases in practice, the jet is not aerated and a vacuum load is added to the pins.

The designer aims to provide an installation which will surely fail before the water surface reaches an undesirable elevation. On the other hand, he does not want failure to occur too soon because that would result in a greater number of replacements. Therefore, he is anxious to design the pins with as great an accuracy as possible.

The authors recommend a modulus of rupture varying from 70 000 lb per sq in. for 3-in. and 2-in. pipe to 80 000 for ¾-in. pipe. The writer found, by tests[7] made prior to 1926, that a modulus of rupture between 42 000 and 58 000 lb per sq in. applied to a number of actual installations utilizing 2-in. to 3-in. pipes. The difference between these stresses and those found by the authors may be attributed to three factors:

(1) The tests made by the writer involved actual cases in which a vacuum occurred under the jet. The amount of the vacuum being unknown, the computed failure stresses of 42 000 to 58 000 lb per sq in. disregarded the vacuum. If this vacuum had not occurred, as in the case of the authors' experiments, the computed failure stress would have been higher.

(2) Present-day manufacture of such pipes requires a descaling operation which involves rolling the pipe in the finishing passes at lower temperatures, which has a tendency to raise the yield point.

(3) Present-day tolerances in pipe thickness are "tighter" than they were formerly. Hence, the average pipe thickness to-day is greater, resulting in greater bending strength.

If water higher than that anticipated would cause damage, the writer recommends the use of the authors' design stresses for the first installation. In all probability the effect of vacuum in the usual clear crest installation will result in the boards failing too soon and the use of somewhat stronger pins in succeeding installations.

Lincoln W. Ryder,[8] **Jun. Am. Soc. C. E.** (by letter).—In August, 1939, in connection with the design and construction of three small flash-board dams for gound-water level control on an open drainage channel, it was necessary to select pins that would fail within a small range in the height of water above the crest of the dam. It was required that the boards remain in place with 1 ft, and certainly fail with 2 ft, of water overtopping them. The purpose of the tests was to determine the maximum bending moments of the pipe specimens chosen tentatively by the designing engineer[9] in order to check and control the variation in overtopping to be expected in the field.

[8] Asst. Engr., Metcalf & Eddy, Boston, Mass.

The apparatus, set up as shown in Fig. 13, differed from the straight cantilever principle utilized by the authors in having two specimens of the same size inserted into opposite ends of a close-fitting pipe sleeve. The load was applied at the middle of the sleeve through a stiff section of I-beam. The sleeve and stiff member simulated closely the action of the cantilever jig in the aforementioned test, there being no appreciable distortion in the sleeve. It is believed that this test rig is simpler than that used by the authors and will yield equally correct results.

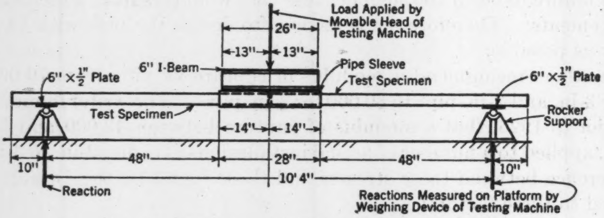

FIG. 13.—METHOD OF TESTING FLASH-BOARD PINS

The low height of the end supports would not allow the bending in the test of the pins to the greater than 20° amount possible in the authors' test; but modifications in this set-up, supporting the ends of the pins farther above the platform of the machine, would allow bends, limited only by the vertical travel of the screw or the ultimate breaking point of the pipe specimen. Such a modification is not necessary for the test as conducted, however, since the maximum bending moment was reached before a bend greater than 8° was made.

The specimens for the first test were 6-ft lengths of 2-in., nominal diameter, standard weight, seamless steel tubing marked "Pittsburgh-P-Seamless Tested 1000 lb. Grade A." Each specimen was inserted 14 in. into the 28-in. long, 2½-in. standard weight seamless tube sleeve, and was supported at points 48 in. from the ends of the sleeve on steel plates and rocker supports.

The specimens for the second test were 2½-in., nominal diameter, standard weight, seamless steel tubing marked and supported as for the first test. The 28-in. sleeve was of 3-in. standard steam pipe.

The results of the two tests, and comparisons with the values recommended by the authors are presented in Table 6. An examination of the results of the two tests shows that a departure from generally recommended design values is to be expected in individual cases. It is important that tests be made of the selected pipe when close control of the water level at failure of the boards is desired, with the thought in mind that a change in design may possibly be made, based on such test results.

The method of testing, using two specimens at one time, tends to give an average value for the modulus, although in the tests described herein the measured deflections showed that the 28-in. pipe sleeve moved downward always parallel to the bed of the machine, indicating the uniform strength of the two specimens.

TABLE 6.—COMPARISON OF TEST RESULTS

Item No.	Description	Test No. 1	Test No. 2
1	Nominal diameter of specimen, in inches	2.0	2.5
2	Maximum load recorded on testing machine, applied at the center of the test set-up, in pounds	1 500	2 600
3	Maximum bending moment,* in inch-pounds	36 000	62 400
4	Section modulus,† S, in inches^3	0.563	1.062
5	Modulus of rupture, $f = M/S$, in pounds per square inch	64 000	58 700
6	Recommended modulus of rupture for use in design (see Table 5), in pounds per square inch	70 000	70 000
7	Recommended bending moment for use in design (see Table 5), in inch-pounds	39 200	74 900
8	Comparison of results, in percentages	8	16

* $M = \frac{1}{2}$ (Item 2) times 48 inches.

† The section moduli were those computed from the standard dimensions for the weights of pipe tested.

Acknowledgment.—Irving Cowdrey, Associate Professor of Testing Materials, Massachusetts Institute of Technology, devised the method of testing and conducted the tests in the laboratories of the Institute; acknowledgment is made for permission to include a description of his rig in this discussion.

E. T. SCHULEEN,[10] ASSOC. M. AM. SOC. C. E. (by letter).—Considerable credit is due the National Hydraulic Laboratory for its tests on flash-boards and to the authors for their suggested methods of rational flash-board design. Apparently, the tests have been conducted in a thorough manner and the use of a full-size flash-board should increase the reliability of the data. It is to be regretted, however, that limitations of discharge in the laboratory precluded tests at higher overflows, particularly at the larger pipe sizes.

The Pennsylvania Water and Power Company conducted a large number of tests several years ago on flash-boards and flash-board pins at its hydroelectric development at Holtwood, Pa. These tests included mechanical bending tests on solid steel pins, wrought iron pipe, standard steel pipe, and extra strong steel pipe of various sizes. Tests were also made to determine the actual water pressure exerted on a flash-board deflected through various angles from the vertical under several depths of overflow.

The mechanical bending tests were conducted in the following manner: The specimen under test was inserted in a socket of 6-in., extra strong, pipe 12 in long. The socket was reinforced at the top with a pipe flange and grouted into a concrete floor. Suitable sleeves were used in the socket to give a snug fit with the various sizes of pipes and pins. The load or pull was exerted at a point 40 in. above the socket and was maintained normal to the specimen throughout the test by connecting the specimen, at the point of pull, through a spring-balance dynamometer to a 4-in. channel, which, in turn, was hinged to a support at the base of the specimen. A pull from a windlass was then exerted on the channel, causing it to rotate with the specimen. The pull normal

---

[10] Hydr. Test Engr., Pennsylvania Water & Power Co., Holtwood, Pa.

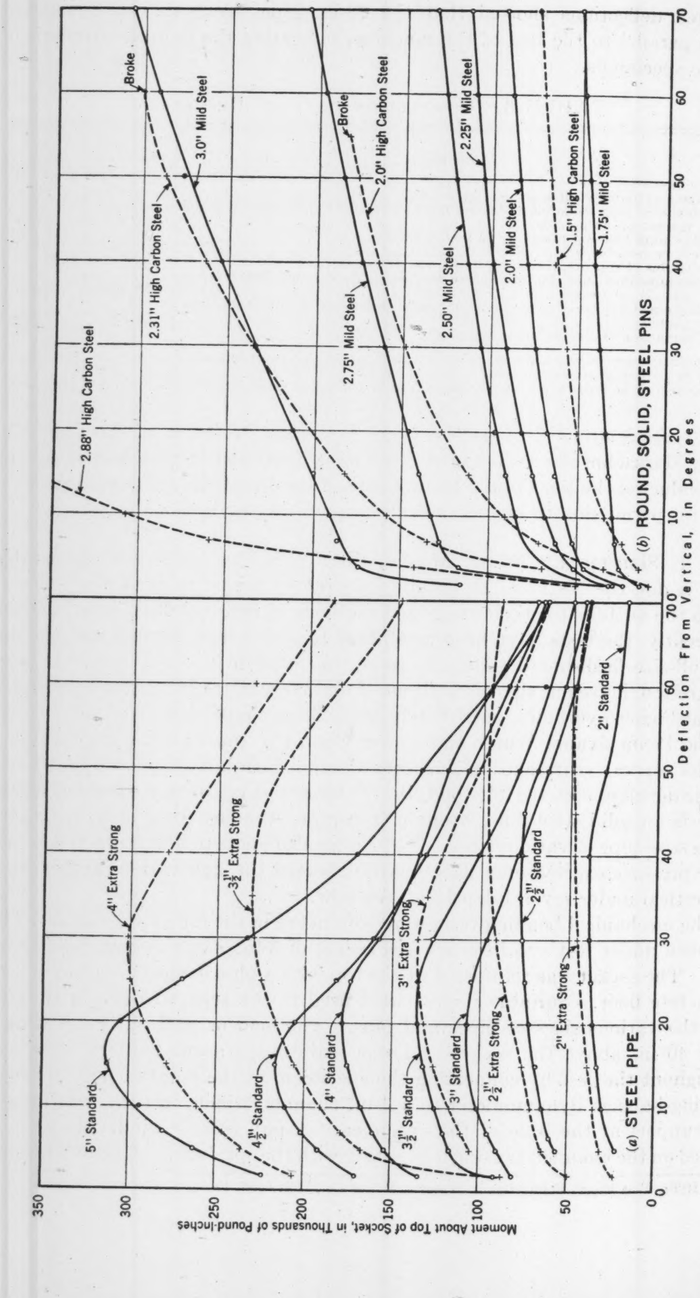

FIG. 14.—RESULTS OF MECHANICAL BENDING TESTS

to the specimen was read on the dynamometer, while the angle of deflection was read on a graduated scale. Since only the resisting moment at the top of the socket is required, the varying load distribution of the hydraulic pressure may be replaced by a single mechanical load such as was done in the test without introducing an appreciable error. Three specimens of each size of pipe or pin were tested and the results averaged.

The results of the tests on steel pipe are shown in Fig. 14(*a*) in which the resisting moment has been plotted against the angle of deflection. The writer feels that nothing is gained in reducing the resisting moment to unit stress by dividing through by the section modulus, which means dividing by a constant for a given pipe size. In addition, such procedure gives misleading stress values, as the actual section modulus is changing continually as deflection progresses. The curves in Fig. 14(*a*) show that pipe is well adapted for use as flash-board supports since the deflection increases with the moment until a definite angle, characteristic for each pipe size, is reached, beyond which the deflection increases while the moment decreases. This is a desirable characteristic which permits the pipe support, once the flash-board deflects to the angle of maximum moment, to bend over, completely and quickly, leaving little obstruction to the passage of water, ice, or debris. Table 7 summarizes the maximum moments and the angles of failure for the various sizes of pipe tests. The resisting moments of the individual test specimens of the same size varied within 5% of the averages given on the curves and in the table.

* Double extra strong. † Extra strong.

The Holtwood tests are comparable with the National Hydraulic Laboratory tests for pipe sizes of 2, 2.5, and 3 in. The angle of deflection at failure is greater in the Holtwood tests than the National Hydraulic Laboratory tests and the value of resisting moment is slightly less.

The results of some typical tests on solid steel pins are shown in Fig. 14(*b*). It is evident from these curves that the continued gradual increase in deflection with increasing moment makes solid pins unsuitable for flash-board supports, as very high forebay levels would occur before complete failure of the pins took place. Another disadvantage is the tendency for the pins to bend from 5 to 8 in. above the socket and thus continue to obstruct the passage of ice or debris after failure. It was found by test that these two difficulties could be overcome by cutting grooves on the front and back sides of the pin at the support, but this method is not practicable. The use of solid pins will usually be far more expensive than the use of pipe.

The computation of moment on a flash-board with overflow after deflection has started, with a normal moment formula, such as Equation (9), is obviously in error since static pressures are attributed to flowing water. An attempt to determine the magnitude of this error was made in a series of tests in Holtwood in which the actual moment of the board was measured at several conditions of overflow.

A test board 2.25 ft wide and 1.8 ft high was placed in a flume of equal width and was rigidly fastened at the bottom to a steel shaft free to rotate in ball bearings. On the outside of the flume, a cast-iron quadrant of 1-ft radius was keyed to the shaft and connected to a spring-balance dynamometer by a thin steel tape running over its edge. The dynamometer, in turn, was connected by a cable to a hand-operated winch. The quadrant and the board were counterbalanced so as to be in balance in any position. A seal of negligible friction at the edges of the board was provided by coating the walls of the flume with paraffin and scraping for close clearances. Four piezometers were placed in a vertical line on the board to indicate the pressure distribution. The board could be held at any angle under various heads and the moment about the bottom of the board, in pound-feet, could be read directly on the dyna-

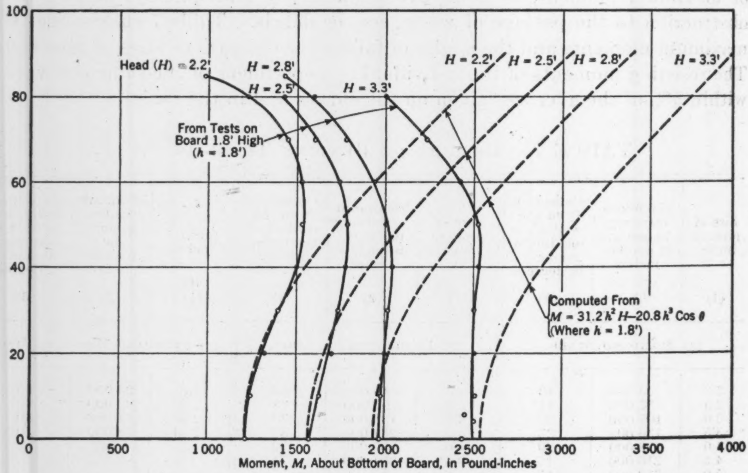

FIG. 15.—COMPARISON OF COMPUTED MOMENTS WITH ACTUAL MOMENTS AT VARIOUS ANGLES OF DEFLECTION

mometer. Tests on the 1.8-ft board were limited to four heads ranging from 2.2 ft to 3.3 ft.

The results of the tests are shown in Fig. 15, in which the measured moments, together with the moments computed from the normal moment formula, are plotted against the angle of deflection. At 2.2-ft head the test moment increases with the computed moment up to a deflection angle of 30° and then decreases, while the computed moment continues to increase. At the higher heads, the point of divergence between the test and computed moments occurs at lower angles of deflection, and at 3.3-ft head there is an appreciable difference at zero deflection. The piezometer readings indicated this reduction in pressure as the angle of deflection increased to be greatest near the top of the board.

An interesting corollary of the tests was the determination of the effect on moment of a vacuum on the down-stream side of the board. Since the test board was not aerated, a vacuum was found similar to that occurring on a long line of flash-boards. Breaking this vacuum by inserting a pipe through the nappe decreased the moment on the board approximately 7 per cent.

JOHN E. FIELD,[11] M. AM. SOC. C. E. (by letter).—In pointing out the uses and desirability of the pipe-supported, collapsible flash-board, this paper is so complete that little remains to be added. The authors are to be commended for the great care with which their research was conducted, and to be congratulated for the very practical conclusions made available to the engineering profession. The writer has used, and caused to be installed, such flash-boards in the spillways of canals and reservoirs, but until he was furnished with advance information and data by the authors, he has hesitated in recommending them unless installed under his personal supervision.

Spillway costs are no inconsiderable part of the entire cost of a dam, and with "fool-proof" collapsible flash-boards that cost is reduced materially and much of the valid objection to flash-boards in spillways will be answered satisfactorily.

The writer has seen many, and has installed some, collapsible flash-boards dependent more or less on mechanical operation, and his remembrance is that few were successful and reliable.

If the dam and spillway are close to a power-plant where experienced men are available at all hours, and especially where there are telephones to give warning of approaching floods, mechanically operated flash-boards in spillways can be tolerated.

The publication of the paper is opportune as records of the size of maximum floods have been considerably changed in the last few years; and ideas of what constitutes necessary spillway capacity have been greatly altered, with the result that the capacity and cost of spillways have been increased materially. Many existing spillways, heretofore considered to be of ample capacity, must be increased in size to conform to the probable maximum flood as determined by the later data.

The failures of more than 100 dams in New England, New York, and New Jersey, in March, 1936, were due to inadequate spillways and are a forceful argument for the re-examination and change in the design of existing spillways. An increased depth by lowering the floor or lip of the spillway with collapsible pipe-supported flash-boards, installed to maintain the necessary height of water in the reservoir, will often be the answer to the new problem.

---

[11] Cons. and Superv. Engr., Denver, Colo.; Engr. Examiner, PWA, Washington, D. C.

Two valid objections to an uncontrolled spillway are the probable loss of stored water, and the difficulty of stopping the outflow after the danger point has passed. These objections can be met in part by so selecting the pipe supports that those most accessible and easily replaced will fail before others. The authors have studied a flash-board so designed that the upper part collapses at a predetermined height of water and the lower part at a higher stage of water level. For a narrow spillway, pipe set horizontally in sockets, in both of the concrete abutments, could be made to support an upper portion of the flash-board independently of the lower portion, and would be free to swing down stream on hinges at the abutments. Local conditions will suggest many variations in the details of the design all based on the fundamentals shown in the paper. The writer has found this type of flash-board very satisfactory in canals, and the description of one actual problem may be of interest.

The cross drainage was taken into the canal primarily to secure the water for storage and also to obviate an expensive culvert or overshot. The cross drainage water from moderate rains could be carried by the canal; but storms were quite common during which the storm water would be in excess of the capacity of the canal to carry it. The proper location for the spillway was at a rock cut, up stream from the cross drainage channel; the lower bank of the canal was cut down to a level 2 ft below the high-water line and pipe supported flash-boards installed in the cut. They were designed to collapse when the water rose 1 ft above the high-water line so that when the pipe failed the wasteway would carry a depth of 3 ft of water equal to the maximum estimated inflow from the cross drainage. Under certain conditions the flood water will flow up the canal and be discharged through the spillway; this prevents an excessive flow below the point at which other cross drainage is probably entering the canal. The plans called for three such wasteways although the canal was provided with a regular wasteway with its floor somewhat lower than the bottom of the canal. This wasteway was provided with slide gates and hand-operated lifting devices.

In 1905, before the pipe-supported flash-boards were proposed, the writer provided wasteways in one large canal by cutting the lower bank, but in lieu of collapsible flash-boards a low earth dam was placed in the spillway. This dam had a crest level 1 ft above the high-water line and washed out whenever overtopped, thereby relieving the canal of its excess of cross drainage water. This design was considered "fool-proof," certain in operation, and easily replaced. The writer is now wondering why he did not think of pipe-supported flash-boards in this case; and he would have profited greatly had the contents of the paper been available to him at that time.

JULIAN H. WHITE,[12] ASSOC. M. AM. SOC. C. E. (by letter).—The extensive tests reported by the authors should help to restore confidence in the use of pipe flash-board pins. Although there is ample evidence that, in the past, their behavior under overflow conditions has been rather unsatisfactory, the results shown in Table 3 indicate that, by the use of the data obtained, failure can be predicted with remarkable accuracy. For practical purposes, a variation of only 2% of the head, as obtained by the authors, would meet every requirement. However, if such close results are expected with conditions different from those under which the tests were made, a better understanding of some factors not evaluated in the paper is necessary. The reduction of pressure at the top of flash-boards, due to overflow, and the rise of water against the flash-boards beneath the nappe can cause an error in head at failure in excess of 2 per cent.

---

[12] Engr., Howard M. Turner, Boston, Mass.

Through the courtesy of Charles M. Allen, M. Am. Soc. C. E., Director of the Alden Hydraulic Laboratory of the Worcester Polytechnic Institute, the writer made a few brief tests to obtain more information on these two factors, and the result may be of interest.

For the tests, a 5-ft glass-sided flume was narrowed to a width of 1 ft for a length of about 14 ft, and a wooden flash-board 1.51 ft high was set in the lower end. The back of the board was faced with a $\frac{1}{16}$-in. brass plate, set with the top above the wood to form a crest, and carefully drilled for 11 piezometers. The piezometers were set in the center of the board 0.010, 0.020, 0.040, 0.080, 0.161, 0.318, 0.450, 0.750, 0.950, 1.200, and 1.451 ft below the crest, and were connected to 0.5-in. gage glasses. Water, measured by venturi meter in a 12-in. pipe, passed through corrugated baffles before entering the flume. The head on the crest was measured by means of a piezometer set in the flume wall about 6 ft up stream from the flash-board, and in some tests was checked with a point gage. In certain runs, where a high velocity of approach was desired, the bottom of the channel was raised to a point 0.50 ft below the crest.

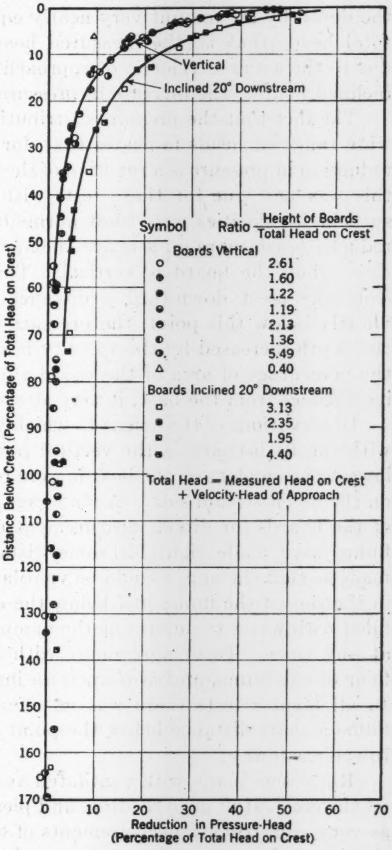

FIG. 16.—REDUCTION IN PRESSURE ON FACE OF FLASH-BOARDS WITH OVERFLOW

Measurements of pressure on the up-stream face of the flash-boards were made both with the boards vertical, and inclined down stream at an angle of 20° with the vertical. The heads ranged from 0.27 ft to about 1.20 ft, and the velocity head in the approach channel varied from 0.001 ft to about 0.13 ft. The results are shown in Fig. 16, in which the reduction in pressure for different points on the boards is expressed as a percentage of the total head on the crest. The tests showed that in the case with the boards vertical the pressure head at the bottom, and for some distance up, was greater than the depth by an amount very nearly equal to the velocity head. Therefore, the total head (that is, the measured head on the crest plus the velocity head due to the average velocity of approach) was used for the reference. With the inclined boards, the increase in pressure at the bottom was not so pronounced.

The fact that the pressure distribution is very nearly the same for a fairly wide range of heads indicates that, for the purpose of flash-board design, the reduction in pressure is a function of the total head on the crest only. Although this was not true for those tests with extremely high velocity of approach, such high velocities would not normally be met in practice. The pressure is reduced much more on a board inclined 20°, its approximate angle a failure, than when the board is vertical. The area affected in both cases extends from the crest downward a distance equal to about one half the head. Shortly below this point, the pressure is the same as for static loading, with the depth increased by the velocity head of approach. With heavy overflow, the percentage of area of the board affected becomes greater, and, because of its distance from the base, it may alter the bending moment considerably.

Observations of the height to which water behind the nappe rises were made with the flash-board in the vertical position only. For these tests, the three lowest piezometers on the boards were reversed so that they measured pressure on the down-stream side. A staff gage was mounted on the down-stream face of the boards for direct measurement of the water height. The sides of the flume were made tight for some distance down stream, and provision was made so that the nappe could be ventilated or sealed as desired. A piezometer in the side of the flume just below the crest was connected to a U-tube partly filled with water to determine the amount of vacuum existing under the nappe at any time. Tests were made with the water falling upon the horizontal floor of the flume, and also upon an inclined floor set at two different angles. In all regular tests there was no effect of back-water. The water left the flume a short distance below the point where it struck the floor, and dropped to the wasteway.

Runs were made with ventilated and unventilated nappe. The flow, head on the crest, staff gage reading, and piezometric heights were recorded, as well as very approximate measurements of the nappe and the angle of the jet with the floor. In the unventilated runs, the vacuum in feet of water existing under the nappe was also measured.

It was noted that when the underside of the nappe was fully ventilated, and no vacuum existed, the water in the gages connected to the piezometers was all at the same elevation. Although the piezometers were set at different heights in the flash-boards, and the water under the nappe was somewhat agitated, the piezometer gages agreed with the staff gage. Thus it was concluded that when ventilated the height of the standing water is a measure of the pressure exerted against the flash-boards, and the distribution is the same as for the static condition.

A. Schoklitsch[13] points out that the rise of water behind the nappe of a weir is not due entirely to the existence of a partial vacuum, but is partly caused by the reaction of the water being turned to its final direction of departure as it strikes the floor. Those tests with the ventilated nappe were analyzed on this reaction basis, and were found to agree very well. The equation given by Schoklitsch indicates heights of the standing water greater than those found, so that another expression was used.

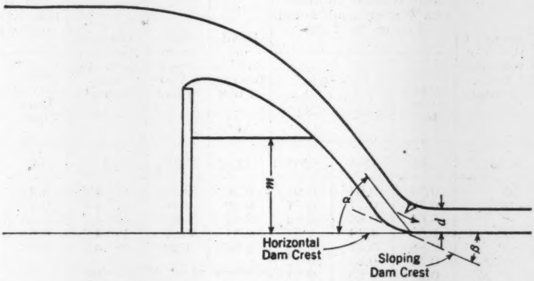

FIG. 17.—STANDING WATER BEHIND NAPPE

Referring to Fig. 17, the reaction of the water flowing at velocity V being turned through the angle α is balanced by the standing water behind the nappe, or

$$\frac{w\,q}{g}\,(V - V\cos\alpha) = w\left(\frac{m^2}{2} - \frac{d^2}{2}\right) \ldots\ldots\ldots\ldots\ldots (23)$$

and

$$m = \sqrt{\frac{2\,q\,V}{g}\,(1 - \cos\alpha) + d^2} \ldots\ldots\ldots\ldots\ldots (24a)$$

Where the sloping floor made an angle β with the horizontal, the equation

$$m = \sqrt{\frac{2\,q\,V}{g}\,(\cos\beta - \cos\alpha) + d^2\cos^2\beta} \ldots\ldots\ldots\ldots (24b)$$

was used. The value of the depth d is quite uncertain because of the curved transition, and with a sloping floor it becomes even more indefinite. The term $d^2\cos^2\beta$ is only an approximation used because greater refinement seemed unnecessary in view of its small value in comparison with the other term under the radical. Equations (24) do not consider losses and certain other phenomena and are therefore not exact. Probably the water behind the nappe above the height d accelerates the falling sheet in the horizontal direction, changing both the angle α and the velocity V. If the true values of these could be determined, other expressions would, perhaps, give better results. For the method used in estimating the reaction height for any particular flash-board installation, and for the few experiments with which it was checked, the formulas given appeared applicable.

---

[13] "Hydraulic Structures," by A. Schoklitsch, published by A. S. M. E., 1937.

The heights of the standing water as observed in the tests under various conditions are shown in Table 8, Column (4). The heights as calculated by Equations (24) from measurements of the nappe made in the tests are shown in Column (5). For these calculations, the measured angle α was used, and the thickness of the nappe at the foot of the fall gave a value for d which was also used to compute the velocity V from the known discharge. The agreement is very good in the tests where the floor was horizontal ($\beta = 0°$) and fair for the inclined floor.

* Using measured nappe dimensions from test.

† Using scaled nappe dimensions from plot of theoretical nappe shape.

In the case of a proposed flash-board installation, the thickness of the nappe at the foot of the fall, the angle of the jet at contact, and the distance of fall, if striking an inclined dam face, would not be known. To see what kind of approximation could be made in this circumstance, values of these unknown quantities for the conditions tested were scaled from a published plot of theoretic nappe shape. The resulting calculated heights of the water are shown in Table 8, Column (6). Although the agreement is not all that might be hoped for, it offers a method of estimating a factor which has been entirely neglected in many flash-board designs. As the moment varies approximately as the cube of the heads on either side of the boards, and as the water rises behind the nappe only a small part of the head on the up-stream side, the discrepancy of 20% shown in some of the computed figures would be much reduced.

The vacuum that may exist under an unventilated nappe can vary over a wide range. Apparently the water continually carries out small amounts of air, and if the fall is low the underside can become completely filled with water, provided there is no means of access for the outside air. The writer made too few experiments to learn just what the pressure conditions are under this circumstance.

When a partial vacuum exists under the nappe, the pressures which occur on the flash-boards are best illustrated by comparison with those obtaining when the nappe is fully ventilated. In the ventilated condition, a given flow caused the standing water to rise against the boards to a height of 0.79 ft, indicated both by the staff gage and the gages connected to the piezometers. With the same flow, but with the nappe sealed, a vacuum of 0.12 ft was observed. The jet was deflected inward approximately 6°, and the staff gage read 1.01 ft above the floor. Gages, connected to piezometers located 0.06 ft, 0.19 ft, and 0.56 ft from the floor, registered pressure heads of 0.95 ft, 0.91 ft, and 0.87 ft, respectively, above the floor. The gage to the upper piezometer differed from the staff gage by 0.14 ft, or about the height of vacuum in feet of water. The gages to the other two piezometers differed from the staff gage by amounts less than the vacuum, probably because of the effect of impact on the lower piezometers which are in a region where the water under the nappe is more disturbed. It is interesting to note that, although the partial vacuum decreases the pressure on the down-stream side of the flash-boards above the standing water, the total pressure due to the standing water itself is greater than it would be if the nappe were completely ventilated. There is still so much uncertainty regarding the question of vacuum that, in the case of a proposed installation, it would seem advisable to provide means to insure ventilation.

To apply the results of these experiments to a practical problem, the writer recalculated the bending moment at failure for Test No. 32, using the reduction in pressure given in Fig. 16. This happened to be the test with the greatest overflow, where the area affected by this reduction would be large. To be sure that the concrete dam used to support the pins had no effect on the pressure distribution, several runs were made using the same flash-board as previously, but with a wooden dam similar to that used in Test No. 32, all built to scale. No difference in pressure was noted.

The total bending moment, including the moment due to the weight of the flash-boards as given in Appendix III, was 44 200 in-lb, which is about 9% less than that computed by the normal moment equation. This gives a modulus of rupture for this test of about 71 700 lb per sq in., which is closer to the recommended value of 70 000 than the value in Table 2(*a*).

If the boards of Test No. 32 had been installed on a flat-crested dam, the standing water behind the nappe would have risen to about 1.9 ft, and this would cause a further reduction of the moment of about 6 500 in-lb. The combined effect of the reduction in pressure on the up-stream face and the back pressure would thus alter the bending moment by about 22 per cent.

Fortunately, the relationship between bending moment and head on the boards is such that the effect of any error in moment on the water-surface elevation is greatly reduced. In many flash-board installations the change in head due to the two factors discussed will be very small; however, where it is important that flash-boards fail within a narrow range, both the reduction in pressure on the face of the boards and the rise of water under the nappe must be considered.

HARRY H. HATCH,[14] M. AM. SOC. C. E. (by letter).—In practice, the authors' simplified horizontal moment formula is used in the design of flash-board pins. The equation is readily obtained from Fig. 10(e), in which $a_1 = \frac{h}{2}$ and $a_2 = \frac{h}{3}$, and it is usually given in the form:

$$M = \tfrac{1}{2}\, w\, h^2\, L \left(H_1 + \frac{h}{3} \right) \ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Expressed in inch-pounds, and with $w = 62.5$, Equation (25) becomes Equation (19b).

The reduction in the value of the modulus of rupture per unit area, with the increase of the pipe diameter, as demonstrated by the authors, is interesting and of vital importance. The authors report a 20% reduction in the unit rupture value between pipes of ¾-in. and 3-in. diameters. This raises the question regarding pipe sizes not within the range of the authors' tests. Will the same rate of reduction in unit value apply to larger diameters? In the absence of laboratory test results with which to answer the question, data from actual structures will be needed. For this reason, the following data may prove useful.

During the flood of September 21, 1938 (with a run-off of 600 cu ft per sec per sq mile), a section of the Cobble Mountain spillway flash-board, 44.92 ft long, functioned properly, in complete accord with its design. The pins consisted of 5-in., standard, wrought-iron pipes, and in this section they were spaced at 4.083-ft centers. The height of the flash-board was 7 ft and $H_1 = 2.25$ ft. Then: From Equation (19b), $M = 343\,840$ lb-in.; from standard pipe tables, $D_e = 5.563$ in. and $D_i = 5.045$ in.; from Equation (1), $S = 5.47$; and from Equation (2), $f = 62.9$ kips per sq in.

The average of the several measurements on some of the pipes resulted in $D_e = 5.60$ in. and $D_i = 5.07$ in., with the corresponding $S = 5.659$ and $f = 60.8$ kips per sq in. The difference in the ultimate unit stresses is around 3% in favor of the theoretical section modulus.

In this excellent paper, only Test No. 24 and Test No. 10(a) were with 2-in., wrought-iron pipes; but there is no value given for either of them under Column (14), Table 2, comparable with the writer's data for 5-in. pipe. It would be of interest if the authors could make this comparison possible.

CHILTON A. WRIGHT,[15] AND CLIFFORD A. BETTS,[16] MEMBERS, AM. SOC. C. E. (by letter).—The interest shown in this paper by the discussions, and by the interesting side-lights revealed, is appreciated.

The description, by Mr. Field, of his flash-board design for handling cross drainage in an irrigation canal was most interesting. Calling attention as it does to the practical applications of flash-boards, this discussion corroborates the experience of others who, since publication of this paper, have advised the writers of the dependable operation of installations based on the paper.

[14] Div. Engr., Springfield Water Works, Springfield, Mass.

[15] Prof., Hydr. and San. Eng., Polytechnic Inst. of Brooklyn, Brooklyn, N. Y.; formerly Hydr. Engr., National Bureau of Standards, Washington, D. C.

[16] Engr., U. S. Forest Service, Washington, D. C.

The formulas developed in the paper will not apply to the pipes set horizontally in the abutments.

The allusion to inadequate capacities of many existing spillways in the light of recent flood data is very important and is receiving consideration by engineers as shown by Mr. Creager in a lecture to the Metropolitan Section of the Society on March 20, 1940.

Hinged Flash-Boards.—The replacements mentioned by Mr. Creager under the heading "Flood of January 1, 1934," become unnecessary if hinged flash-boards are used. Since the publication of the paper (in May, 1939) a large number of such installations have been made in various parts of the United States. Instead of being satisfied with charging the loss of flash-boards that float away at high water to the added power head obtained from the use of these flash-boards, even for a period of a few days, some power companies are using hinges and are saving the boards as well as the power.

Other Tests.—The method of test described by Mr. Ryder is ingenious, but it had been tried by the writers and found wanting. When the use of pipes for pins was first considered by the U. S. Forest Service, two specimens each of galvanized-iron pipe, 3 in. and 4 in. in diameter, were tested in a 200 000-lb machine on a set-up similar to that described by Mr. Ryder. The 3-in. pipe was placed on rounded supports on a 14.4-ft span and loaded in the center by means of a 4-in. pipe 20 in. long, representing the socket support. The distance from the socket pipe to the support was made equal to the computed distance to the point of application of the water pressure (flash-board height 3 ft, overtopping head of water 4 ft). The machine loads were divided by 2 to obtain an average value for each pipe as a cantilever.

The maximum stresses determined by this test (58 700 lb per sq in. and 47 300 lb per sq in. for the 3-in. and 4-in. pipe, respectively) were considerably lower than the later mechanical test results shown in Table 2(*b*). The 3-in. pipe attained a maximum stress of 74 000 lb per sq in. in the mechanical test and 73 000 lb per sq in. in the hydraulic tests (Table 2(*a*)).

The maximum stresses were obtained at a measured deflection of 17° which was the same value as shown in Table 2(*b*) for the 3-in. pipe. However, the pipes were not broken, although they were bent to the limit of the machine, 45 degrees. It is believed that this method of testing cannot be depended upon to give stresses suitable for use in the design of flash-board pins. Actual hydraulic tests are much to be preferred.

The discussion by Mr. Schuleen was much appreciated by the writers, who had previously had access to the comprehensive test data of the Pennsylvania Water and Power Company. Although the methods of mechanical testing described by Mr. Schuleen differed from those of the writers, the principal results (maximum loads and deflections) are in general agreement.

The writers are in full agreement, that the characteristics of standard pipe make it structurally and economically adapted to use for flash-board support. Tests of steel pins made prior to the pipe tests disclosed how a small variation in the chemical make-up of steel pins can have a large and hazardous influence on failure head in the field. Commercial pipe, on the other hand, has a tolerance that requires little checking.

The characteristic definite deflection for maximum moment is shown for the results of the standard pipe tests. The value of 20° agrees closely with the writers' values in Table 2.

Although Equations (19*b*) and (20) presuppose the direct use of the resisting moment, it is thought that the computation of the stress from the maximum moment (using a section modulus based upon the original dimensions of the pipe) is of value in two ways. It determines the variation among individual pipes of a given size and also aids in determining a suitable average value to be used in design with tabular standard values of section modulus for a specified pipe size. The cantilever loading method of making mechanical tests seems to agree better with the hydraulic tests than the double cantilever method of testing.

The original data loaned to the authors from the Pennsylvania Water and Power Company included a large number of actual field tests of pipe-supported flash-boards on the Holtwood Dam. The recorded failures were at heads giving stress values in the pipes slightly lower than indicated in the mechanical tests of the company.

Mr. Hatch has reported an interesting field test on the Cobble Mountain spillway in which wrought-iron pipes were used. For purposes of comparison with the value of 62.9 kips per sq in. found by Mr. Hatch, the maximum stress computed by the simplified moment formula for Test 24 in Table 2 should be 56.3 kips per sq in. The value for Test 10*b*, 60.6 kips per sq in., was determined directly by mechanical test. Since steel pipe was much more readily available than genuine wrought iron, particularly in small sizes, it was adopted for test and was used by the Forest Service.

Pressure Reduction on Front of Flash-Boards.—In the data on actual dynamic pressure of the flowing water on the inclined flash-board (Fig. 15) it is to be noted that no noticeable variation from the assumed (static) pressure occurred up to a deflection angle of 20°. An interesting comparison is brought out by relating the maximum deflection attained before an appreciable departure from the theoretical value occurred, to the percentage of overflow head, $\frac{H - h}{h}$. The results in Table 9 show that, for all the overflow tests except possibly that of the 2-in. pipe, the error due to neglecting the dynamic effect of the water was negligible.

Mr. White's experiments were very interesting, showing an intelligent attack upon the perplexing question of the effect of pressure changes on flash-board action. Fig. 16, plotted in dimensionless terms, certainly emphasizes the hydraulic similarity of pressures on flash-boards made to different scales. For all ratios of length of boards to head on crest, the points seem to lie on the same curve (see Fig. 16). For any vertical board a pressure reduction of 10% can be expected at a distance below the top equal to 15% of the total head. This could be interpreted to mean that the pressure at a point 0.06 ft below the top of a 5-ft board with 0.4 ft of water going over the top would be reduced in the same amount as for the same point on a board 1 ft high with the same head. Although this seems difficult to believe, further inspection of Mr. White's tests might ascribe it to the added head of velocity of approach. The computation of the resulting total pressure would have to be made by integrating along the established pressure curve, such as, for example, Mr. White's determination of moment for Test 32, Table 2(*a*).

The reduction of pressure at the top of the flash-boards due to overflow, which is so well covered by Mr. White, is an interesting side-light but such a minor factor that it can be ignored except in unusual cases of very high approach velocities. For practical flash-board design the total head on the crest is sufficient.

Partial Vacuum Behind Flash-Boards.—Mr. Creager's able analysis of the lower stresses produced by flash-board pins tested under partial vacuum explains the variation of these from the writers' results. One of the reasons for running the tests described in the paper was the difficulty encountered when attempting to operate an installation based on Mr. Creager's table. The 42 000 lb per sq in. just did not apply to the standard pipe being used, which had a modulus of rupture of 70 000 lb per sq in.

The finding, indicated by Mr. Schuleen, that vacuum under the nappe decreased the moment approximately 7%, checks with findings at several installations that have been reported to the writers.

The paper did not attempt to analyze the effects of vacuum because in some cases on actual dams the pressure on the down-stream side of the boards is decreased, creating a "pull," whereas in others enough back-water is drawn up beneath the nappe to counteract this effect. Furthermore, the effect of vacuum can be readily corrected by the use of heavier pipe, the size of which can be computed from the observed failure head. Where it is impractical to ventilate the nappe, it is advisable to provide for larger sockets in case the heavier pipe becomes necessary.

As a practical matter, the degree of vacuum obtained would depend upon the height of the flash-boards, the clearance at end of the crest, the width of the flat channel immediately below the boards, and other factors, and should receive consideration in design of an installation. The effect of this vacuum would be to cause an earlier failure of the pins—that is, it would be on the safe side. Since an attempt to make an allowance for vacuum may very readily lead to the pipe failing at a higher head than desired, the recommendation in the last paragraph of Mr. Creager's discussion, which is also made in the original paper, should be emphasized.

In conclusion the writers wish to thank all those who have aided in shedding some light on the design of flash-board installations.

EFFECTIVE MOMENT OF INERTIA OF A RIVETED PLATE GIRDER

BY SCOTT B. LILLY,[1] M. AM. SOC. C. E., AND SAMUEL T. CARPENTER,[2] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. WILLIAM R. OSGOOD, CLYDE T. MORRIS, B. R. LEFFLER, E. NEIL W. LANE, LEWIS E. MOORE, W. E. BLACK, L. E. GRINTER, CHARLES M. SPOFFORD, E. MIRABELLI, EDWARD GODFREY, WALTER H. WEISKOPF, C. D. WILLIAMS, ALVIN B. AUERBACH, JONATHAN JONES, R. L. MOORE, J. M. GARRELTS AND I. E. MADSEN, FRANCIS P. WITMER, A. W. FISCHER, J. R. SHANK, HAROLD D. HUSSEY, CHARLES U. KRING, THOMAS C. SHEDD, AND SCOTT B. LILLY AND SAMUEL T. CARPENTER.

SYNOPSIS

The importance of the plate girder as a structural member has warranted many tests of its behavior under load. As an approach to the solution of this problem, a series of tests was planned to discover, if possible, how much the flange stresses in plate girders are affected by the rivet holes in the flanges. In other words, it is an attempt to find what, in this report, is called the effective moment of inertia, and, as far as the writers know, is the first attempt to secure such information. This report describes the methods used at Swarthmore College, at Swarthmore, Pa., for testing two plate girders and gives a resumé of the results. The intent was to obtain knowledge of the action of a plate girder under working conditions; therefore the girders were not loaded until they failed.

Both sets of tests show that the effective moment of inertia is very close to the gross moment of inertia, and that a good correlation of measured flange stresses with calculated stresses exists if the gross moment of inertia is used. Some data are also presented to justify the location of the neutral axis at the center of gravity of the gross cross-sectional area. Finally, the writers present a formula for effective moment of inertia.

NOTE.—Published in October, 1939, *Proceedings*.

INTRODUCTION

It is customary for structural designers to consider a net moment of inertia in the design of plate girders. For the purpose of this paper, "net moment of inertia" will be defined as the moment of inertia computed by deducting the effect of the material removed by holes in the tension flange. For clarity, "gross moment of inertia" is defined as the moment of inertia of the solid cross section of the plate girder, allowing no deductions for the effects of holes in the tension flange. The use of "net moment of inertia" in connection with the beam theory implies a displacement of the neutral axis that can be computed. The net moment of inertia assumes that holes on the gage lines of the tension flange are slotted for the full length of the girder. It is needless to say that the usual plate girder, having a rivet pitch in the flanges of from 2.5 in. to 6 in., does not represent a girder with slotted holes the full length of the tension flange. The practice of designers, who use the "gross moment of inertia" when computing the deflection of a plate girder, has been confirmed by some experimental data.

To secure an answer to the question of whether the net moment of inertia or the gross moment of inertia, or an intermediate value which may be called the effective moment of inertia, should be used in the determination of the flange stresses of a plate girder, the same section of the same plate girder was tested under pure moment with the flange in the following condition:

Series A, solid flanges (no holes in outstanding legs of flange angles or in cover plates);

Series B, open holes in outstanding legs of flange angles and in cover plates;

Series C, with machine bolts in the holes described in series B; and,

Series D, with rivets in the holes described in series B.

It is evident that if the same section of the same plate girder is tested under the conditions described as series A, B, C, and D, any displacement of the neutral axis will be disclosed by the strains in the web and in the flanges.

TEST GIRDERS

The choice of test girders was predicated upon maintaining a depth-to-span ratio consistent with practice, at the same time selecting a size that could be handled readily in the laboratory. The test girder chosen has a depth-to-span ratio of 1 : 10.6. Fig. 1 is a detail drawing of the test plate girder, PT-1, and represents the girder in the state in which it was received at the laboratory. The holes marked "A" were drilled in the shop after tests A1, A2, and A3 had been completed. Test girder, PT-2, was the same when received, except that the rivets connecting the web plate to flange angles in the pure moment section were spaced 2.5 in. apart. No holes were punched in the outstanding legs of the flange angles or in the cover plates in the center section of the girders. The make-up of the girders was the same throughout the full length, namely:

1. Web plate........	12 in. by $\frac{5}{16}$ in.
4. Flange angles......	2.5 in. by 2.5 in. by $\frac{1}{4}$ in.
2. Flange plates......	6 in. by $\frac{1}{4}$ in.
2. Flange plates......	8 in. by $\frac{1}{4}$ in.

The depth, back to back of angles, was 12.5 in.; and, 8-in. cover plates were used so that strains could be measured on the side of these plates next to the 6-in. cover plate. This procedure gave no useful information and was abandoned.

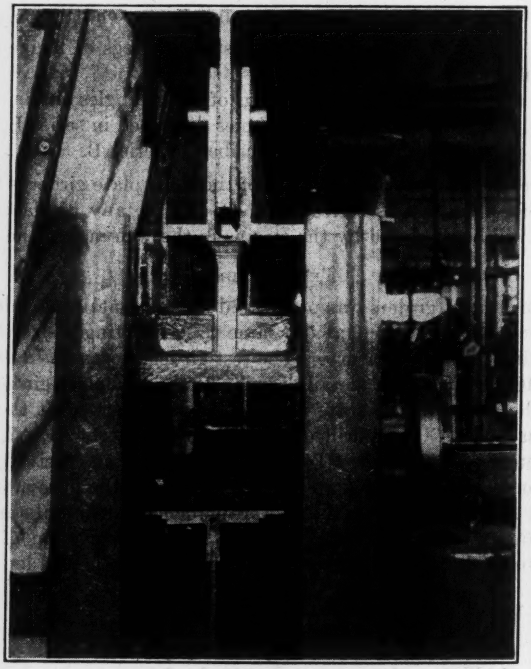

FIG. 2—VIEW OF TEST SET-UP, SHOWING THE FLANGE PLATE-CLAMPS IN PLACE

The "pure moment section" of the test beam was the only one in which the four comparative conditions of girder section could be secured. The cover plates were developed under the conditions of series A and B by bolts in the shear section only. Fig. 2 illustrates the typical installation of the flange clamps necessary to prevent the flange plates on the compression side from buckling during series A and B. The clamps were designed so that two $\frac{3}{8}$-in. set-screws came into point contact with the flange plates and two $\frac{3}{8}$-in. set-screws came into contact with the inner side of the outstanding legs of the flange angles along the gage lines. The plates were pulled into contact and held there by the clamps. Their construction was such that they added nothing to the flange area.

Description of Test Set-Up

The method of applying the loads was as follows: One end of the test girder rested upon a roller upon the platform of a 100,000-lb testing machine; the other upon a fixed cylindrical reaction point, supported by a steel trestle and adjusted to the same height as the platform of the testing machine. The load was applied to the test girder by an equalizer beam (see Fig. 3) through rollers situated at points 33.5 in. from the supports at each end of the test girder. (Test loads are noted in all cases, in this paper, as P and not 2 P. Therefore the bending moment in the pure moment section is always 33.5 P in-lb.) The load was brought to the middle of the equalizer beam by a loading beam. One end of this loading beam was connected to the movable head of the testing machine by a clevis and pin; the other end was attached to the corresponding end of the plate girder by two bolts, 1.75 in. in diameter, passing through steel slabs, top and bottom, contact being made through cylindrical reaction points. Contact between the loading beam and the equalizer beam was made by means of a roller. By this arrangement the concentrated load applied at each load point is exactly that which is weighed on the testing machine, making possible a total load of twice the rated capacity of the testing machine. In the presentation of data the testing machine load is the recorded value. In all cases, the total load on the girder is twice this value. The east end of the girder (see Fig. 3) rested on the testing machine.

Pure Moment Section.—The method of measuring the deflections in the pure moment section was as follows: Two pins (0.25 in. in diameter), spaced $25\frac{1}{8}$ in. each side of the mid-point of the girder, were passed through the web plate in such a manner that the tops of the pins were level with the center line of the web plate. These pins extended through the web plate sufficiently far on each side so that they could support steel side bars 1½ in. by ¼ in. in cross section. The holes in the ends of these bars were ¾ in. in diameter, and the distance between the supporting pins was 50.25 in. At the middle of the plate girder a third pin was placed through the web in a similar manner, and on each end of the pin was mounted an Ames dial, reading to $\frac{1}{10{,}000}$ in., with the contact points resting upon the side bars. (These dials are identified as the north and south dials.) Under this condition of loading, the middle of the test girder was subjected to a uniform moment, if the moment due to the weight of the girder itself is neglected. It is evident that the reading on the dials gave the deflection of the center line of the web below two points on that line which were spaced 50.25 in. apart (see Fig. 1).

To measure the stresses in the girder itself, gage points with 10-in. centers were drilled and readings taken with a 10-in. strain gage having a least reading of $\frac{1}{60{,}000}$ in. Assuming a modulus of elasticity of 30,000,000 lb per sq in., the least reading was equivalent to a stress of 50 lb per sq in. In the test procedure, readings were checked by independent observers until they agreed within six divisions on the dial, insuring readings with a maximum deviation of 300 lb per sq in.

TEST PROGRAM

Fig. 4 shows the cross sections of the plate girder for each series of tests. In each case an initial load was applied and then the load was increased until the increment of deflection in the pure moment section was 0.0300 in., or slightly greater. After each series had been run, with loads to give the aforementioned deflection, the load was increased to 63,000 lb for series C-3 and D-3 for specimen PT-1, and readings were taken in the pure moment section. A detailed statement of the test program follows:

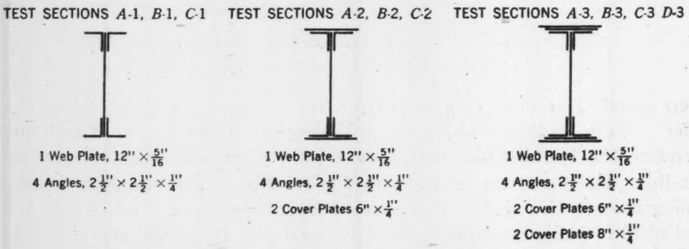

FIG. 4.—TYPICAL CROSS SECTIONS AND STRUCTURAL MAKE-UP OF THE TEST SPECIMENS

Test Section	Description (see Fig. 4)
A-1	Web plate with two pairs of flange angles riveted on, but with no holes in the outstanding leg.
A-2	6-in. cover plate added top and bottom. There were no holes in the plates in the

Test Section	Description (see Fig. 4)
	pure moment section. The plate was held in contact with the flange angles by the clamps shown in Fig. 2.
A-3	8-in. cover plate added to the 6-in. cover plate, top and bottom. In this case, also, the pure moment section had no holes in it and the plates were held in contact by the clamps.
B-1	Web plate and flange angles were tested as in test section A-1.
B-2	6-in. cover plates added, clamped, and tested as in test section A-2.
B-3	8-in. cover plate added to the assembly described in test section B-2, the two plates clamped and tested as in test section A-3.
C-1	$\frac{5}{8}$-in. machine bolts placed in the open holes ($\frac{11}{16}$ in. in diameter) of the outstanding legs, tightened with proper washers, and tested as in test specimen B-1.
C-2	6-in. cover plates added, bolted on, and tested as in test specimen B-2.
C-3	8-in. cover plate added to the assembly described under test specimen C-2 and tested as in test specimen B-3.
D-3	The two cover plates were riveted to the flange angles and tested as in test specimen C-3.

In series B (the section with open holes), the plate girder with the 6-in. and 8-in. plates attached was taken to a drill press and holes were drilled through the outstanding leg of the flange angles and the cover plates, in both compression and tension flanges. In specimen PT-1 the pitch was 5 in.; and in specimen PT-2 the pitch was 2.5 in. In series B, the holes were open in the pure moment section. (The pitch of the rivets in specimen PT-2 was first made 5 in. as in specimen PT-1, and tests were run which checked specimen PT-1 so closely that they are not reported herein. Then the girder was returned to the drill press and the additional holes drilled to make the pitch 2.5 in.)

Neutral Axis

Beginning with the assumptions of the common theory of flexure, it can be proved that the neutral axis must pass through the center of gravity of the cross section of a beam under flexure. This is substantially correct for homogeneous beams of the usual kind. However, in the design of riveted plate girders, the engineer must decide whether he will locate the neutral axis at the center of gravity of the gross cross section, or at the center of gravity of the net cross section, considering that the material that filled the holes has been removed from the tension flange, and that the holes in the compression flange are completely filled. If the net cross section existed at each section, as it would if it were obtained by slotted holes running the full length of the girder, and if the compression flange were solid, the center of gravity should undoubtedly be computed from the net cross section. The net section is not continuous, however, and it is questionable whether the rivets fill the holes of the compression flange sufficiently to consider the compression flange as solid.

That the neutral axis remains near the center line of the web plate is shown in Table 1, where data from tests on the two plate girders, PT-1 and PT-2, are presented. The observed results were obtained by measuring strains on 10-in. gage lines on both sides of the web plate. The gage lines were at distances of 1 in., 2 in., and 3 in. above and below the center line of the girder. A straight line was passed through the plotted data and the deviations obtained directly. The deviation of the neutral axis was also computed using the measured strains of the outside fibers of the girder, and these results are compared with those obtained from the web data. The experimental results all indicate that the neutral axis deviates only slightly from the center line of the web plate, and not as it has been considered to deviate by the designers using the net section. This means that the deformation of the compression flange is almost as great as that of the tension flange.

TEST COUPONS

Tensile tests were made by the National Bureau of Standards on eight test coupons from specimen PT-1, obtained from the extra pieces of material sent by the fabricator (see Table 2). The coupons had a reduced width of 0.5 in. and a gage length of 2 in. The coupons for specimen PT-2 were tested at Swarthmore College. The results were so similar that the data are omitted for present purposes. The average value of the modulus of elasticity was 30,000,000 lb per sq in.

OBSERVED EFFECTIVE MOMENTS OF INERTIA

In the pure moment section, the deflection in a length of 50.25 in. was read to the nearest 0.0001 in. by Ames dials. To observe values of the effective

moments of inertia, the moments of inertia of the gross section, I_G (Column (2), Table 3), were assumed to be correct for series A, and a load, P_G, was applied until the deflection in the pure moment section was 0.0300 in. In series B, C, and D, loads were applied to each test section of the correct value to cause a deflection of 0.0300 in. Then it was assumed that since the deflection, Δ, of the plate girder was the same in each of these tests, and since $\Delta \propto \frac{P}{E\,I}$,

$$\frac{P_G}{P_o} = \frac{I_G}{I_o} \qquad (1)$$

and the observed effective moment of inertia in each case is

$$I_o = \frac{P_o}{P_G} I_G \qquad (2)$$

in which P_o and I_o are the load and moment of inertia for any particular section. For example, the load that caused a deflection of 0.0300 in. for section A-2 was 26,600 lb and the gross moment of inertia was 315 in.^{4}; the load that caused the same deflection for section B-2 was 25,200 lb. Therefore, the observed effective moment of inertia for section B-2 is $I_o = \frac{25{,}200}{26{,}600} \times 315 = 298.5$ in.^{4}

In this manner, values of the observed effective moment of inertia for each test section were computed and tabulated in Column (1), Table 3. In comparing the values in Table 3(*a*) and Table 3(*b*), it should be recalled that the pitch in this pure moment section was 5 in. for specimen PT-1 and 2.5 in. for specimen PT-2. Instead of tabulating in Column (2), Table 3, the value of the gross moment of inertia opposite the test section of series A, the value of I_o was computed from the value of the deflection, 0.0300 in., as determined by the moment-area method, using the value of E as determined from the test coupons. These values check the values of the gross moment of inertia within the limits of the experimental error and justify the foregoing procedure.

When the values of the observed effective moment of inertia are plotted, the graphs show that they approach the values of the gross moment of inertia as the tests proceed from that giving the greatest deviation in series B (open holes), through series C (bolted sections), to series D (riveted sections). The deviation is a very small value in series D—namely, 2.1% of the gross moment of inertia for specimen PT-1 and 7% for specimen PT-2.

* Neutral axis eccentric. † Neutral axis at center. ‡ Top flange. § Bottom flange.

FLANGE STRESS

In all of the test sections, flange stresses were obtained experimentally by measuring strains in the top and bottom flange. A 10-in. strain gage was used, with the gage lines placed symmetrically with regard to the longitudinal center line of the girder. Four gage lines were used for test sections A-1, B-1, and C-1, six gage lines for test sections A-2, B-2, and C-2, and eight gage lines for test sections A-3, B-3, C-3, and D-3. The layout of the gage lines on the 6-in. and 8-in. cover plates was such as to allow two gage lines to bisect the open holes in the flanges and later the bolts and rivets. The observed flange stress was computed from an average of the readings on all gage lines in every case, using the observed value of modulus of elasticity. The stresses were computed for a single load for each series, as follows:

Test sections	Load, P, in kips
A-1, B-1, and C-1	15.9
A-2, B-2, and C-2	26.6
A-3, B-3, C-3, and D-3	41.6

These particular values were selected because they caused an increment of deflection of 0.0300 in. in test sections A-1, A-2, and A-3 for specimen PT-1.

Using these loads the flange stress has been computed using the gross moment of inertia; using the net moment of inertia with the neutral axis at the center of the web plate; and finally using the net moment of inertia with the neutral axis at the center of gravity, considering the compression flange as solid and the tension flange as slotted.

The stresses computed by using the gross moment of inertia are compared with the observed stresses in Table 3, Columns (5), (6), (9), and (10). The computed flange stresses are somewhat lower than the observed stresses for all sections except for the initial solid flanges of series A. For those sections a good correlation exists. The stress in the compression flange is greatest for open holes, and gradually approaches the computed value as the method of holding the flange together is changed from clamps, to bolts, and to rivets. No such decrease is shown for tension flange. This probably indicates that bolts and rivets tend to relieve the stress in the compression flange.

In Table 3, Columns (5), (6), (13), and (14), the observed flange stresses are compared with the flange stresses computed using the net moment of inertia, with no shift allowed in the location of the neutral axis from the center line of the web plate. The computed flange stresses are about 2,000 lb per sq in. higher than the observed stresses throughout this comparison.

A comparison between the observed stresses and the flange stresses, computed by using the designer's net moment of inertia (see "Introduction") and assuming the neutral axis to be above the center line of the girder, in accordance with some design procedures, is shown by Table 3, Columns (5), (6), (11), and (12). The agreement between the compression flange stresses is very good. However, the computed stress for the tension flange is approximately 4,500 lb per sq in. higher than the observed. This would seem to indicate that this design procedure would give much larger flange areas than are needed to maintain safe stresses in the tension flange.

In addition to the foregoing information, Table 3 gives the flange stresses computed by the observed effective moment of inertia, using the observed deviation of the neutral axis as given in Table 1 from observed flange data. The excellent agreement between this column and the observed flange stress is an independent check on the observed results.

ACTION OF GIRDER UNDER HIGHER LOADS

After completing the tests where the loads were held to values giving a flange stress of about 20 kips per sq in., test sections C-3 and D-3 of specimen

PT-1 were subjected to loads causing flange stresses of 30 kips per sq in. The load was increased and decreased by increments, and strain readings were taken in the flange on both the up loading and the down loading.

The strain readings gave no indication of permanent set. A breaking of the scale around the rivet heads through the upstanding legs of the flange angles was noticed. A close observation showed a perfect set of orthogonal slip lines. No such breaking of the scale was noticed around the rivets through the flange plates, although this region was stressed higher. It is to be remembered that the holes in the cover plates were drilled, whereas the holes through the web and flange angles represented shop practice of punched holes. An investigation of one of these holes showed poor alinement of the plates and a very rough perimeter. Is it possible that the condition of the holes accounts for the observed strain lines?

STRESS CONCENTRATIONS

Stress concentrations, with their accompanying areas of plastic flow around the holes in the flanges of a plate girder, present some questions in regard to the validity and the interpretation of the strain gage readings explained herein. As treated in this paper strains have been reduced to terms of stress by applying Hooke's law. There may be objections to this procedure on two grounds: (1) That this does not represent the stress at any point; (2) that the average stress through the net section represents the true stress. In answer to these objections, the writers would point to Fig. 5, showing the way the stress varies across the net section. It is known that the maximum stress reaches the elastic limit, and further there is nothing that can be done about it; second, a unit stress arrived at by using a net area has no meaning.

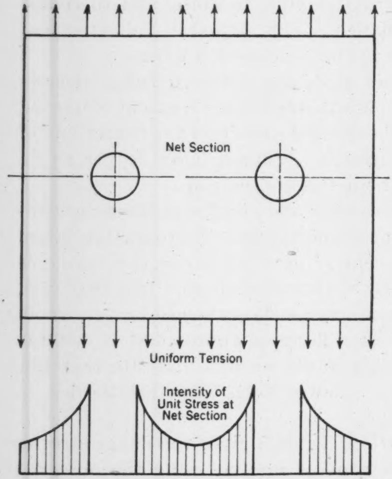

FIG. 5.—STRESS CONCENTRATIONS

It is reasonable to assume that any strain gage, operating on a 10-in. gage length over the holes, will register some plastic, as well as elastic, deformation. The writers do not know how to separate these components. A. Nadai states that the areas of plastic flow in the region of a hole are in the shape of a cross, the direction of the cross making an angle of approximately 45° with the principal stresses of tension or compression.[3] It is also well known that the intensity of stress is highest at the boundaries of the hole, which are on a diameter perpendicular to the applied principal stresses. Fig. 5 depicts this condition graphically. As the principal stress is increased, the stress at the boundary of the hole increases to the yield point value and plastic flow begins in the areas defined by the cross.

---

[3] "Plasticity," by A Nadai, McGraw-Hill Book Co., Inc., New York, N. Y., 1931, p. 103.

For any reasonable allowable design stress, the yield point stress will be reached at the hole, and plastic flow will occur. The designer's choice of 18 kips per sq in. instead of 20 kips per sq in. will not prevent this from happening, although it may limit, to some extent, the area over which plastic flow may extend.

Once a ductile material is strained beyond the yield point and the load is released, residual stresses are set up which will be beneficial in resisting the next applied load.

EFFECTIVE MOMENT OF INERTIA

It seems reasonable to believe that both the strength and the stiffness of a plate girder are affected by the size and spacing of the rivet holes in the flanges of a plate girder. If the pitch were small enough there would be a slot the full length of the girder, and if the diameter of the rivet holes were large enough there would be no material to carry the load. The writers have developed the following formula which incorporates the results of the tests described in this paper, and which contains terms that include the effect of the diameter and pitch of the rivet holes.

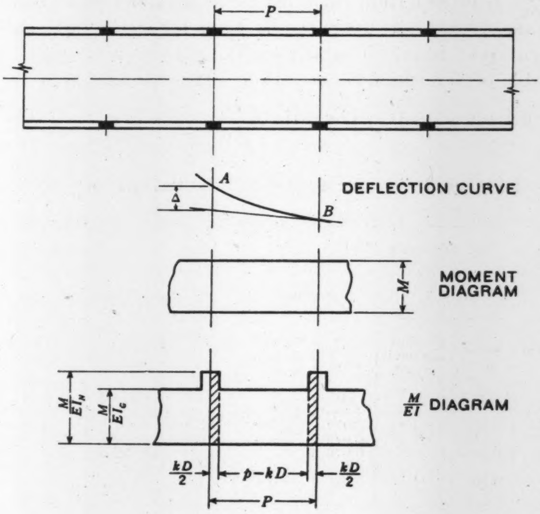

FIG. 6

Referring to Fig. 6, let L = length; M = moment; p = rivet pitch; D = diameter of rivet holes; $k\,D$ = the part of the rivet hole that is acting as a full net section; Δ = the deflection by point A with reference to a tangent to the elastic curve at point B; I_G = gross moment of inertia; I_C = clear moment of inertia (holes are deducted from the top and bottom flanges); and I_E = effective moment of inertia. The new term, I_C, the "clear" moment of inertia, has been introduced since these tests show that the neutral axis remains at the middle of the web plate. This fact is based on the practically equal stresses in the top and bottom flanges. By moment areas:

$$\Delta = \frac{0.5\,P\,M}{E}\left(\frac{p - k\,D}{I_G} + \frac{k\,D}{I_C}\right) = \frac{0.5\,P\,M}{E}\left[\frac{p + \left(\frac{I_G}{I_C} - 1\right)k\,D}{I_G}\right] \quad \text{..(3)}$$

In general, $\Delta = \frac{M\,L^2}{E\,I}$ times a constant; and, in the present case:

$$\frac{L}{I} = \frac{P}{I_E} = \frac{P + \left(\frac{I_G}{I_C} - 1\right)k\,D}{I_G} \quad \text{..................(4)}$$

That is,

$$I_E = \frac{I_G\,p}{p + \left(\frac{I_G}{I_C} - 1\right)k\,D} \quad \text{....................(5)}$$

The quantity $k\,D$ in Equation (5) must be determined experimentally. The value of k probably depends upon D, the diameter of the hole, and g, the distance between rivet lines. The writers do not have enough experimental results available to determine this relation. It is thought that the value of k must lie between 0.6 and 1.0. The ratio of $\frac{I_E}{I_G}$ is called "m." Table 4 shows the value of "m" obtained from experimental data compared with the computed "m," using k equal to 1 and 0.6, respectively. It will be noted that the percentages of deviation of the computed value from the observed value change

TABLE 4.—COMPARISON OF VALUES OF $m = \frac{I_E}{I_G}$

from positive to negative with these values of k; that is evidence that k has a value between 0.6 and 1.0.

CONCLUSIONS

1.—The measured flange stresses are smaller than the computed stresses using a "net" moment of inertia based upon a deduction of rivet holes from the tension flange. In the case of the girder with a 5-in. pitch, the difference was considerable; with the girder having a 2.5-in. pitch there was a closer correlation. This was anticipated and furnishes some evidence that an effective moment of inertia should depend upon the rivet pitch as well as the rivet diameter. The net moment of inertia, used in design with top and bottom flanges alike, should yield conservative stresses.

2.—The experimental values of the effective moments of inertia are less than the computed gross moment of inertia. The effect of rivet pitch is shown clearly. However, the test girder having the 5-in. rivet pitch and riveted flanges gave nearly an exact agreement between the experimental and computed values of the moment of inertia.

3.—The tests indicate that the neutral axis should be assumed at the center of gravity of the gross cross section.

4.—The effective moment of inertia can be computed by using the theoretical expression, Equation (5), which involves the rivet pitch. Further experimental evidence is needed to establish this conclusion, and the value of $k\,D$.

5.—Since stress concentrations reaching the yield point must exist as soon as the unit stress in the gross section approaches the stress ordinarily specified for structural work, and nothing can be done to prevent them, the writers believe that design methods should be made as simple as possible. Any method that may be adopted must give sections that have been proved in practice to be satisfactory.

It is believed that the data from these tests point to the acceptability of the gross moment of inertia for design purposes. For ordinary girders, under usual loadings, it requires no modification; for cantilever girders, or girders with small pitch, it should be used with a coefficient such as is indicated by Equation (5).

It is hoped that this paper will stimulate discussion of this subject and reveal additional data which may confirm or disprove these findings. Many engineers may have an opportunity to measure strains and deflections of full-size girders. If this could be done widely, and such data carefully studied, all uncertainties would soon be removed.

ACKNOWLEDGMENTS

The investigators wish to acknowledge the cooperation of The American Institute of Steel Construction in conducting this research project. F. H. Frankland, M. Am. Soc. C. E., and all members of the Research Committee have contributed many suggestions that have been incorporated in this study. The writers are particularly indebted to A. R. Wilson, M. Am. Soc. C. E., engineer of bridges and buildings, of the Pennsylvania Railroad Company, for his sympathetic and timely discussions during the preparation of the paper.

Mr. D. F. Windenburg, physicist at the Bureau of Construction and Repair of the U. S. Navy Yard in Washington, D. C., has cooperated throughout the project. His assistance in making several tension tests on riveted plate specimens is acknowledged. Robert DeMoyer, Assoc. M. Am. Soc. C. E., a graduate student at Swarthmore and an associate professor of civil engineering at Pennsylvania Military College, at Chester, was of great assistance while performing the tests. Mr. Paul Kutz and Mr. G. A. Bourdelais, of the Swarthmore Engineering Division, are responsible for many of the details developed during the set-up of the testing equipment. The Belmont Iron Works, Philadelphia, Pa., performed the final riveting of the test girders free of charge.

DISCUSSION

WILLIAM R. OSGOOD,[4] M. AM. SOC. C. E. (by letter).—In discussing the interesting and valuable paper by Professors Lilly and Carpenter, it may not be out of place to call attention to a paper by Friedrich Hartmann.[5, 5a] This paper treats the question theoretically and discusses a test made in 1891 in the light of the theory. Professor Hartmann comes to the conclusion that in the absence of considerations of fatigue, girders of symmetrical cross sections may be designed safely on the basis of gross moment of inertia. In the case of an unsymmetrical cross section with a heavier compression flange than tension flange, however, deductions should be made for the rivet holes in the tension flange.

The authors state that loads causing flange stresses of 30 kips per sq in. gave no indication in the strain readings of permanent set. Was any such indication noted in the readings of deflection?

It seems quite possible, as the authors suggest, that the condition of the holes in the web and flange angles might account for the observed strain lines around these holes. It is likely that severe initial strains due to punching existed around these holes, and also, if the holes were not completely filled by the rivets, higher strains under load would be expected than otherwise. The strain lines might appear in the upstanding legs of the flange angles and not in the outstanding legs because the latter were connected to plates with drilled holes. The drilled holes would probably tend to a less erratic variation of strain in the plates, and this tendency would affect the strain in the connected legs of the angles in the same way since strains in adjacent connected parts cannot be wholly independent of each other.

The authors state that it was their intent to obtain knowledge of the action of a plate girder under working conditions. Knowledge of the maximum load a girder can carry and the type of failure, particularly the behavior of the compression flange, is also so important that it would have been fortunate if this additional information could have been obtained for the girders tested.

CLYDE T. MORRIS,[6] M. AM. SOC. C. E. (by letter).—Professors Lilly and Carpenter are to be commended for the care with which their investigations were conducted and the completeness with which they have published the data secured. Experiments of this kind are important in extending the knowledge of strength of materials and confirming practical methods of design.

Presumably, the observed fiber stresses given in Column (6), Table 3, were computed from strain gage readings and, therefore, represent the average fiber stress over the 10-in. gage length. For girders PT-1 the holes in the outstanding legs and cover plates were spaced 5 in. apart, and therefore two holes would be included in the 10-in. gage length. Counting the holes as $\frac{11}{16}$ in. square (instead of round), which is on the safe side, the computed average fiber stress is $\frac{1}{10}\left[2 \times \frac{11}{16} \times \text{(Net I) stress} + 8\tfrac{5}{8} \times \text{(Gross I) stress}\right]$. For girders PT-2 the holes were spaced 2½ in. apart and the computed average fiber stress is $\frac{1}{10}\left[4 \times \frac{11}{16} \times \text{(Net I) stress} + 7\tfrac{1}{4} \times \text{(Gross I) stress}\right]$.

B-2	18.4	20.8	19.7	20.9	18.73	19.06
B-3	19.1	21.5	20.2	21.0	19.43	19.76
C-1	17.2	19.5	18.2	19.2	17.52	17.83
C-2	18.4	20.8	19.6	20.3	18.73	19.06
C-3	19.1	21.5	19.9	20.9	19.43	19.76

Table 5 gives the stresses in the bottom flanges taken from Table 3 and as computed by the method just given. In every case the observed average stresses given in Column (6), Table 3, are greater than the computed stresses using the foregoing method, and are only slightly smaller than the stresses using the net moment of inertia.

From these tests the writer would draw the conclusion that the customary method of design, using the moment of inertia of the net section with the neutral axis at the center of gravity of the gross area (Column (14)), gives results only slightly on the side of safety, and that the use of the moment of inertia of the gross section (Column (10)), as recommended by the authors, is dangerous.

B. R. LEFFLER,[7] M. AM. SOC. C. E. (by letter).—Conclusion 5 of this paper—that for ordinary girders, under usual loadings, the tests indicate the acceptability of the gross moment of inertia for design purposes—is fallacious, and the writer will attempt to show where the false reasoning occurs.

For many years structural engineers have known that the calculated deflection of the ordinary plate girder, using the moment of inertia of the gross section, gives results which correspond closely to the results found by testing. The false reasoning lies in assuming that deflection is a true indication of stress in a riveted girder.

To understand the meaning of what follows, it should be remembered that the deflection of a plate girder is caused principally by the shortening of the compression flange, and the lengthening of the tension flange.

To show the fallacy more clearly, consider a bar, 100 ft long, 6 in. wide, and

---

[7] Engr. of Bridges, N. Y. C. R. R. Line West of Buffalo, Cleveland, Ohio.

0.5 in. thick, with a 1-in. hole at the middle and on the axis of the bar. If the bar were stressed to a given amount, a certain total stretch of the bar would be obtained. Now, if a similar bar of the same quality of metal, without a hole in it, were stressed to the same amount, the total stretch of this bar would not differ appreciably from that obtained for the bar with a hole in it; the longer the two bars, the closer would be the agreement in the total stretching. Consider the bars as reduced to a length of 1 ft, the hole still remaining in one of the bars: It is probable that the total stretch in the two short bars would differ considerably.

If the investigator confines himself to bars 100 ft long, he would be justified, apparently, in concluding that a hole in a tension bar does not weaken the bar. This reasoning is entirely as valid as the reasoning leading to Conclusion 5. In fact, the writer regards most static tests on riveted structural parts to be of little value as a guide to correct designing, particularly if most of the stress is caused by a live load.

The fact is that engineers have not yet learned how to design, correctly, a simple tension bar with one hole in it when such a bar is subject to frequent live loads. Even a tension bar without a hole cannot have a uniform distribution of stress, for the reason that any rolled material is subject to surface defects which act as stress raisers. About all that is known about a bar under tension is the amount of average stress across the bar.[8, 9]

Had the authors subjected the plate girder to an enormous number of repetitions of live load, they probably would not have reached Conclusion 5.

The ultimate average unit stress in any tension member can be determined only by the use of repeated loads, varying through a wide range of values. For a polished small specimen, the average unit stress will approximate the actual maximum unit stress; but such polished material is never used in actual structures.

The value of the average unit stress is a function of the range of stress and the number of applications. For a standard, Messrs. Wilson and Thomas[9] selected 2,000,000 applications. The average unit stress which produces failure after 2,000,000 applications is the ultimate strength of the material.

The authors have placed too much emphasis on the experimental location of the neutral axis. The location of the neutral axis can be varied over quite a wide range without materially affecting the results of calculation of stress in a plate girder, particularly in a deep girder. The internal resisting moment must equal the external moment. This internal resisting moment is a couple, the arm of the couple being the distance between the centers of gravity of the compressive stresses and the tensile stresses. The neutral axis is nothing but a dividing point between the compressive stresses and the tensile stresses; and this point is at the apexes of two triangles, granting the usual theory of flexure of a bent beam. Hence, a considerable variation in the location of the neutral axis can be made without affecting, to a great extent, the arm of the internal

[9] "Fatigue Tests of Riveted Joints," by Wilbur M. Wilson and Frank P. Thomas, Eng. Experiment Station, *Bulletin No. 302*, Univ. of Illinois, 1938.

couple. It is to be remembered, also, that the sum of the internal tensile stresses must equal the sum of the internal compressive stresses, and this fact alone is of much more importance than the exact location of the neutral axis.

The paper may lead to erroneous specifications. The desire to save metal and simplify the designing of a riveted plate girder is a strong inducement to consider Conclusion 5 as valid.

E. NEIL W. LANE,[10] ASSOC. M. AM. SOC. C. E. (by letter).—The importance of such basic experimental evidence as that supplied by the authors is seldom appreciated properly. Engineers, like men in other scientific groups in the search for truth, delve into detail to such an extent that sight is often lost of the major theme. Naturally this lays a weaker foundation in the form of an increased number of assumptions necessary to proceed with further detail. Messrs. Lilly and Carpenter have done a good job of attracting the attention of the profession to a major theme of structural design.

There has been considerable argument as to the relative merits of designing plate girders on the basis of the gross or net moment of inertia; and the younger, more inexperienced, and generally theoretical minded portion of the profession have tended to favor the more complicated and less accurate design procedure.

It is more or less common among structural engineers to use the gross moment of inertia in computing deflections because it will generally give a more reliable result than will the use of the net value. The authors have proved the experience that neither is exactly correct and that the users of the gross moment of inertia are nearly right. The experience of field engineers with full-sized girders under actual working conditions serves as further corroboration that the gross moment of inertia is nearly correct within the elastic or design range.

Use of the net moment of inertia has led to additional safety at the expense of appreciable economy, a false idea as to design accuracy, and a misrepresentation of the stress distribution.

The fabricating methods now in use are the best that can be obtained at a reasonable cost. For this reason, riveted plate girder flanges will always consist of many small areas (adjacent to the rivets) of high stress restrained and stiffened by surrounding areas of low stress. It should be emphasized that use of the girder causes a plastic flow of the metal at points of extreme stress that makes the girder more capable of withstanding repeated loading. Drilling of members in place and the use of turned bolts is a dream for any but unusual conditions. Welding, although a step in the right direction for continuity and distribution of stresses, has evils of its own that limit its use.

The authors are to be commended for including the effect of diameter and pitch of flange rivets in their proposed formula for the effective moment of inertia. However, the writer would like to see the authors' studies include the effect of various ratios of fabrication—such as, depth to span length, web thickness to depth, and flange area to web area.

---

[10] Junior Civ. Engr., National Advisory Committee for Aeronautics, Phoebus, Va.

Lewis E. Moore,[11] M. Am. Soc. C. E. (by letter).—The experimental determinations were made by measurements of deflection under varying conditions and certain conclusions are drawn, particularly with regard to design, that seem to call for discussion.

According to the laws of mechanics, deflections and flange stresses in a beam are interdependent, and, in general, therefore, the deflections should be in proportion to the average flange stresses. By average flange stress is meant the average, considering not only gross and net areas, but the proportion of length which each governs; in other words, it must be a weighted average.

Considering the ordinary plate girder, the net area of a flange governs only on a plane perpendicular to the flange and passing through the centers of the rivet holes. If this plane is pushed parallel to itself along the axis of the flange the net area will increase until, when the plane becomes tangent to the rivet holes, it becomes equal to the gross area. This gross area will govern until the plane becomes tangent to the next set of rivet holes. A simple method of obtaining the average flange area is to compute the volume of the flange between successive clusters of rivets, less the volume of the rivet holes. Using the girder of the experiments, and omitting the web, the 5-in., flange rivet spacing yields the following:

Description	Area, in square inches
2, 2½-in. by 2½-in. by ¼-in. angles	2.38
1, 6-in. by ¼-in. plate	1.50
1, 8-in. by ¼-in. plate	2.00
Gross area	5.88

The gross volume, center to center of rivet holes, is 5.88 in. by 5 in. = 29.40 cu in. The area of an $\frac{11}{16}$-in. rivet hole is 0.37 sq in., and the total length of holes is (¾ in. by 2) + (¼ in. by 2) = 2 in., making the volume of one set of rivet holes equal to 0.37 sq in. by 2 or 0.74 cu in. Subtracting this from 29.40 gives 28.66 cu in. net volume of steel between rivet holes.

The average flange area for the 5-in. length then is $\frac{28.66}{5} = 5.732$ sq in. The moment of inertia of the cross section will vary directly with the flange area. The deflection varies inversely as the moment of inertia. The ratio of the effective moment of inertia to the gross moment of inertia is then determinable from the average flange area, and theoretically, in the case in question, should be equal to $\frac{5.73}{5.88}$ or 0.975. This corresponds to the quantity "*m*" given by the author. For the particular experiment D-3 with dimensions of riveting as in the foregoing on the girder, "*m*" is given as 0.98.

This is a close agreement between theory and experiment and, incidentally, is a confirmation of the ideas of those who have believed it correct to compute deflections from gross moments of inertia.

The authors' conclusions regarding the position of the neutral axis agree with an opinion expressed by the writer in 1913.[12] The reasoning then was that the net section exists over only a short proportion of the beam and that between rivet holes the position of the neutral axis is certainly found by using the gross area. It seems entirely reasonable to assume that the neutral axis does not shift up and down at every rivet hole, but remains in substantially the same vertical position throughout the length of a properly designed beam. It seems reasonable, furthermore, to assume that this position will be nearer to the neutral axis of the preponderating section, which is the gross section.

---

[11] Cons. Engr., Boston, Mass.

[12] "Design of Plate Girders," by Lewis E. Moore, 1913, p. 42.

The question of the propriety of using the gross moment of inertia or the effective moment of inertia for designing is a quite different one.

The author states that conditions of stress on net areas through rivet holes are variable, and that the metal is stressed, in part, beyond the elastic limit at these locations, using customary working stresses.

As a simple illustration of what happens, consider the application to the experimental girder. Suppose the effective moment-of-inertia method is adopted, with the value determined by the experiment, which is 0.98 of the gross, and only the flange is used. With a design stress of 18,000 lb per sq in. one should use 18,000 × 0.98 = 17,640 lb per sq in. to calculate the gross moment of inertia, and to proportion the flange. The net area (with $\frac{11}{16}$-in. holes) of the flange is 5.88 − 1.02 = 4.86 sq in. The net area is then $\frac{4.86}{5.88} \times 100 = 83.0\%$ of the gross. This means that the average stress on the net area is $\frac{17,640}{0.830} = 21,200$ lb per sq in., or about 18.0% above the allowable of 18,000. In view of the fact that there is some unavoidable overstress at the rivet holes when designing in the usual way with usual stresses, it is doubtful if the effective moment of inertia method is proper to use when designing.

For quick designing by the section-modulus method the writer has found that, for ordinary plate girders, it is sufficient to determine the section by applying 85% of the allowable tensile stress to the moment and then using the tables for moments of inertia of gross sections. The designs so determined rarely need much revision of the main sections.

W. E. Black,[13] Jun. Am. Soc. C. E. (by letter).—While engaged in testing one-quarter size steel rigid frames at Lehigh University at Bethlehem, Pa., in 1938, the writer had occasion to investigate the effective moment of inertia that was being obtained in the tests. For one test specimen, a length of girder having constant cross section was tested as a simple beam loaded symmetrically with two equal concentrated loads. In the part of the beam having maximum moment, top and bottom flange strains were observed at various points, and the extreme fiber stresses were computed from them. The effective moment of inertia, as computed from these stresses, was found to be less than 3% smaller than the gross moment of inertia, and comparatively greater than the net moment of inertia. The cross section of the model girder at the location being tested was 6 in. deep, and consisted of a 6-in. by $\frac{5}{32}$-in. web plate and four 2-in. by 2-in. by $\frac{1}{4}$-in. angles, riveted together by 0.5-in. rivets having a pitch of 3 in. This section, although small, represents a girder of decidedly different proportions than that tested by the authors, and it is gratifying that results obtained in the two cases were similar.

---

[13] Instr., Dept. of Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.

The method of computing the effective moment of inertia used in connection with the aforementioned rigid frame tests was based upon an empirical relation that has been used previously by some designers. In this method, the volume of metal removed by the rivet holes in a given rivet line is considered to be uniformly distributed along the length of the girder at the same distance from centroidal axis as the rivet line. Thus, the reduction in moment of inertia of a given section due to one line of rivets would be, approximately:

$$\Delta I = \frac{A_h\, g}{p}\, d^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which ΔI = reduction in moment of inertia due to the rivet line; A_h = cross-sectional area of rivet hole; g = grip of rivets; p = pitch of rivets; and d = distance from centroidal axis to center of rivet line.

In applying this relation, the neutral axis was assumed to remain at the centroidal axis of the gross section and the deductions were made from top and bottom flanges alike. This computed effective, or average, moment of inertia gave agreement within 1% of the experimental value of moment of inertia determined by the foregoing test.

To test the applicability of this simple method further, the writer prepared Table 6, which is based on the authors' tests. The experimental values are taken directly from the data presented in the paper. The computed values of $m = \frac{I_E}{I_G}$ (see Table 4 and accompanying explanation in the paper) and of the flange stresses were calculated using the effective, or average, moment of inertia just described. It will be noted that the comparisons are made for only the bolted and riveted sections, which may be expected to simulate an actual plate girder in behavior. The comparisons show that the computed average moment of inertia falls within approximately 1% of the experimental moment of inertia for test section PT-1, having a rivet pitch of 5 in., and within 4% for test section PT-2, having a rivet pitch of 2.5 in. The observed and com-

TABLE 6.—EFFECTIVE MOMENT OF INERTIA

puted values of flange stresses have a maximum divergence of 5% for any given section. It will be noted that the agreement obtained for the riveted sections is considerably closer than for some of the bolted sections.

The writer does not offer this method for determining the effective moment of inertia of a girder section in place of the authors' or any other theoretically sound formula, but rather to supplement such formulas as a simple working relation that will achieve approximately the same results. It is of interest to note that the values of $m = \frac{I_E}{I_G}$ computed by this method agree very closely with those computed by Equation (5), for $k = 0.6$. Regarding the application of any method for determining effective moments of inertia, the writer concurs with the authors that in the ordinary case, gross section may be used for design without fear of serious error. In those instances where the amount of material removed from a plate girder by rivet holes is unusually large, the test data indicate that an effective moment of inertia should be used. The method of determining the effective moment of inertia to be used in such cases requires, for complete justification, further tests on girders which have greater percentages of material removed by rivet holes, and from both the web and the flanges.

Many engineers, admitting the advisability of using an effective moment of inertia for the computation of girder deflections, still insist upon a net section when computing stresses. There is some basis for this stand in that the actual stresses existing adjacent to a rivet hole are probably much greater even than those computed by the use of net section. Were the structural failure of a plate girder to occur by rupture across a transverse row of rivets, the use of net section would be justified. However, since the structural failure of a plate girder, under static loads, will occur, not by rupture, but by the general yielding of a comparatively large portion of the girder near the location of maximum moment, the high local stresses near the rivet holes and the high average stress across a transverse row of rivets lose much of their significance. Many tests have borne out this predication. Therefore, the observed flange stresses obtained by the authors using a 10-in. gage length, although not the actual maximum stresses, are the significant stresses when the prospective failure of the girder is being considered. The agreement between the observed flange stresses and those computed using the observed effective moment of inertia (see Table 3) is evidence enough that the effective moment of inertia may be used for computing stresses.

L. E. GRINTER,[14] M. AM. SOC. C. E. (by letter).—The profession is indebted to the authors for prompt publication of these tests on plate girders. Recent changes in design specifications preceding the publication of these tests but possibly to be justified thereby, have upset standard procedures in plate-girder design and, naturally, have disturbed conservative designers. Net section, as well as its importance in design, has been taught to engineering students since the beginning of engineering education, and its sudden elimination from certain accepted specifications was too startling to be accepted without question. It is evident, therefore, that these tests, which are considered practically to justify the use of the gross moment of inertia, will be inspected with the greatest care.

---

[14] Vice-Pres. and Dean, Graduate Div., Armour Inst. of Technology, Chicago, Ill.

It is first noted that the two girders tested were only 12 in. deep. Hence, even the theoretical displacement of the neutral axis was a fraction of an inch, and the observed displacement was too small to be measured consistently by the available measuring devices. Another objection to a shallow girder as a built-up member for testing purposes is that the strains introduced by fabrication would produce a disproportionate influence upon the test results. The irregularities in Table I would undoubtedly have appeared far less serious if the girder had been several times as deep. For instance, rivet slip, if it had occurred, would represent a serious influence upon the test results for these shallow girders.

Neutral Axis.—Consistency is evident in the test results, reported in Table 1, in that all data indicate a small shift of the neutral axis in one direction. This shows the care with which the tests were made and confirms clearly the long-held belief that some deduction from the gross section is necessary to allow for the influence of holes whether open or filled. The fact that strain measurements were made on a 10-in. gage length which spanned from two to four rivet spacings indicates that the authors were not attempting to do more than determine an average eccentricity of the neutral axis. The second important observation from Table I is that the location of the neutral axis, as obtained from flange measurements, does not agree with the location as found from web strains. Since these strains were obtained from a section where the shear was zero, one can only conclude that there must have been some rivet slip, or the theory of "plane sections" failed to apply for some other unknown reason. This is rather disturbing if conclusions are to be drawn from these data.

If one notices that the average observed displacement of the neutral axis for all recorded data on specimen PT-1 is about one sixth or one seventh of the computed displacement, an important observation can be made. This specimen had $\frac{11}{16}$-in. holes at 5-in. spacing. Hence, less than one sixth of the length of the girder was influenced by the net section, and the observed "average" displacement of the neutral axis was of the magnitude that should have been expected. Whether the neutral axis actually shifts upward at each hole in the flange is questionable, perhaps, but the influence in added flange stress must be considered in design until it is proved non-existent. Such proof is still lacking. Fig. 7 shows, pictorially, the possible shift in the neutral axis above a flange hole. Proof of this action is also non-existent at the present time.

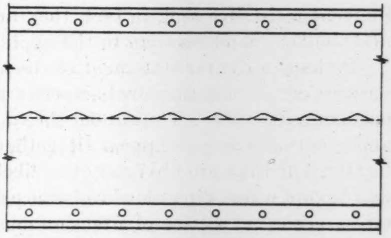

FIG. 7.—POSSIBLE UNDULATIONS OF NEUTRAL AXIS

Effective Moments of Inertia.—The method used to measure the effective moment of inertia was based upon the observation of deflection. Of course, this indicated, accurately, the proper moments of inertia for use in future deflection calculations, but it scarcely seems significant for maximum stress determination. A deflection is produced by the cumulative influence of the stress at all cross sections. Since a major part of the length of the girder functions as a solid cross section without holes, it is self-evident that the effective moment of inertia, when determined from measured deflections, will represent an "average" moment of inertia which will approach the gross moment of inertia closely. Surely there can be little connection between this "average" moment of inertia and the proper value for use in the flexure formula.

Flange Stress.—Again dependence is placed upon a 10-in. strain gage and recorded values are carefully determined averages of the readings taken from four to eight gage lines. Recorded values, therefore, do not represent even the greatest "average" strains for 10-in. gage lengths. What maximum strain would have been recorded on a shorter gage length is purely speculative. Naturally, it would have been higher than the "average" values recorded, which are from 2,000 to 4,500 lb per sq in. lower than computed values from net moment of inertia. It is clearly within the range of probability that strains could have been measured on ½-in. gage lengths quite as high as the theoretical values. In fact, considering possible torsion in the cross section, it would not be particularly surprising to find measured strains that exceeded the theoretical strains for gage lengths of 1 in. or less.

Stress Concentration.—There has been much confusion about the subject of stress concentrations, and discussions of rivet-hole stresses have not been free of such influence. There are high stresses around punched rivet holes, and there would be high stresses even if plastic distortion had not taken place during punching. However, residual stresses from temperature change, or from overstrain, and even stress concentrations from discontinuities, are unable to resist load. A tension member with a hole may have a high localized stress, but this stress does not increase the load capacity (in fact, it reduces it) because the average stress over the net area A_n is still $\frac{P}{A_n}$. In exactly the same manner the stress concentrations around the rivet holes of a plate girder do not produce moment resistance and, in fact, they are more related to fabrication methods and similar influences than to the applied moment.

Perhaps a clearer statement of the action of stress concentrations, residual stresses, etc., is that they are balanced stresses—that is, tension and compression occurring together. Thus under the smallest plastic flow they begin to reduce, and eventually they disappear altogether. Such stresses are not to be neglected lightly, but they are obviously less likely to produce failure than direct stress and flexure where direct load resistance is involved. Statics requires the average stress on the net section of a tension member to be equal to the load divided by the net area. The laws of statics permit no loose thinking in this matter, and it would be a very incautious investigator who questioned this fact or permitted test data to change his thinking in this regard. Perhaps bolts could be tightened through holes in a tension member with sufficient pressure to reduce the net effect of the holes, but engineers are not likely to be willing to let this possibility influence their belief that tension members must be designed for net section.

The lower flange of a girder is as much a tension member as is a chord eyebar of a truss. In fact, it serves the same purpose. Apparently any argument about stress concentration resisting load that can be applied to one can be applied to the other. Any thought that stress concentration over the entire section of the tension flange which is an increase of "average stress" can be neglected in the same way that residual stress and stress concentration around rivet holes are neglected is subject to serious criticism since it conflicts with the requirements of statics. Admittedly, this increase of stress over the section of the tension flange at a rivet hole may exist over a very short length of the flange and may scarcely be found at all when measurements are made over a 10-in. gage length. However, like a weak link in a chain, the effect upon the whole is serious, as statics demonstrates unerringly.

Further Tests.—It is not beyond the reach of modern testing methods to determine accurately the influence of rivet holes upon "total" or "maximum" flange stresses as distinguished from the authors' determination of "average" flange stresses over a 10-in. length of span. With sensitive gages, strains could be measured on $\frac{1}{2}$-in. gage lengths at a dozen or more positions across one section of the web and the tension flange in line with a rivet hole. It would be preferable to perform this test under light loading so that the problem of inelastic strain near rivet holes would not be involved. Then, by transferring unit strain into unit stress and by summing the total stress over the flange and web section, it would be possible to check either the so-called approximate or exact methods of plate-girder design. Such a test, to be most useful, should be made on a test girder of reasonable depth, as representative as possible of standard construction. Of course, there could be no particularly useful design information obtained from single deflection measurements because deflection is a measure of average resistance, whereas the interest in the present case is in the resistance of a particular section. The final check on the accuracy of such testing is obtained from statics. The total moment resistance of the section obtained as the summation of the moment resistances of its fibers must equal the applied bending moment.

Specifications.—Specifications should follow, and not lead, theory. Testing a procedure by introducing it into specifications before it has been checked by statics, well substantiated by tests, and even by use, is dangerous from more than one point of view. The questionable use of the gross moment of inertia in plate-girder design is a case in point. The influence upon the cross section is so minor that it is not likely to endanger a structure physically, but it seems to the writer that its introduction into specifications was far more serious, in that it tended to develop mental carelessness. The laws of statics are fixed matters that must not be changed by specification writers. When working stresses are to be increased, they should be straightforwardly raised, but "design moments" which are controlled by statics should not be reduced even if the influence upon the structure is the same. The profession suffered from the use of that artifice in flat-slab specifications, and there is no reason to reestablish a similar practice with reference to plate girders. The next step would be to omit the consideration of net section in tension members. Of course, this is no criticism of the authors' tests, which were undoubtedly well planned and carefully performed. The criticism is of premature use of anticipated results by specification writers.

CHARLES M. SPOFFORD,[15] M. AM. SOC. C. E. (by letter).—The writer has read this paper with much interest and wishes to commend the authors for their careful investigations and excellent report. That such investigations are needed is shown clearly by the fact that standard specifications for plate-girder design in the United States are not yet stabilized with respect to the allowance for rivet holes or the position of the center of gravity.

The authors' experimental method of determining the position of the center of gravity of the girder was such as to give the average moment of inertia over the central part of the girder only. In this part of the girder the bending moment is uniform, no web splice occurs, and there are no vertical lines of rivets except at the ends of the section. The results show clearly that under these conditions the centers of gravity of the girders tested lie nearer midheight than when determined by computations of the net section based upon deducting rivet holes in the tension part of the girder only. The calculated values given by the authors, however, give only the location of the center of gravity of a section through rivets, whereas the average center of gravity would be higher than this since rivet holes do not occur at every section.

For the girders tested, with rivets at 5-in. pitch in the vertical legs of the flange angles only, the position of the average center of gravity would be considerably greater than that computed by the authors and would conform quite closely to observed values. This would apply in lesser degree in cases where the rivet pitch is reduced to 2.5 in.

The writer feels that the results of the tests are scarcely sufficient to warrant definite conclusions for use in actual design. The girders tested were somewhat out of line with those generally employed in practice, since the section modulus of the web was much larger in proportion to the total value of the moment of inertia than is common in actual plate girders, particularly in bridge girders. This condition is especially true in the part of the girder in which the measurements were made, since the shear in this part of the girder was zero. Moreover, the weakest section of a large plate girder is generally at a web splice, and it would have been desirable if the authors could have included some tests for the value of I and the position of the center of gravity of the girder at such a splice.

The authors' conclusion that the data from these tests point to the acceptability of using the gross moment of inertia in design involves the conclusion that either the allowable unit stress should be reduced, or that rivet holes do not weaken a girder, which latter conclusion the writer believes designers will be slow to accept. It is to be hoped that Messrs. Lilly and Carpenter will find it possible to make additional tests along these lines.

[15] Hayward Prof. of Civ. Eng. Mass. Inst. Tech., Cambridge; Cons. Engr. (Fay, Spofford and Thorndike), Boston, Mass.

E. MIRABELLI,[16] M. AM. SOC. C. E. (by letter).—These tests show the effect of flange holes, bolts, and rivets on the deflection and on the average flange stress of a plate girder when subjected to pure bending by a static loading which induces average stresses within the elastic limit of the material. It is questionable if they show how the average flange stress at a critical section is affected by the presence of holes or rivets, particularly in a region subjected to the combined action of bending moment and shear. The tests are of definite value in contributing toward an understanding of plate-girder action, and there is no intention of disputing their importance. However, it is doubtful if this set of tests, by itself, provides enough information to form a sufficient basis for changing the current design practice of using net girder section. Following are some reasons why it appears to the writer that caution is warranted in abandoning the usual design procedure:

(1) The effective or observed moments of inertia given in Table 3 are based on observed deflections which are affected by all sections of the girder—those between rivet holes as well as those at the rivet holes. Such values of the effective moment of inertia are averages for the girder as a whole. They are proper ones to use in computing deflections, but are not correct for evaluating the stress at a critical section through rivet holes. The flange stress computed by the beam formula, using such a moment of inertia, is not the critical stress; it is some kind of an average stress. Similarly, the observed flange stresses that were measured with a 10-in. gage are the averages of stresses on all sections within the length of the gage. They are no indication of the average stress on a section passing through the rivet holes. It seems reasonable to assume that failure follows when the stress exceeds some critical amount on a single section without necessarily extending over an entire region. To prove this it is necessary only to test a perforated or riveted bar in tension and find that failure occurs on a section through the hole.

(2) The girders were tested in bending only, without simultaneous shear. Consequently, the flange rivets were not subjected to any stress due to flange-stress transfer which accompanies an increment in bending moment. Such rivets act simply as stitch rivets to hold the angles and cover plates together. Any stress that exists in the rivets is that due to initial tension in the shank caused by cooling, and whatever stress occurs in the rivet head through friction at the surface of contact with the plates or angles. The condition of the rivet is similar to that indicated in Fig. 8 in which a rivet is shown holding together four plates which are subjected to end forces, *F*. The only possible stress path across the gap, *G G*, is through the rivet heads. The strength of such a connection may be calculated if assumptions are made regarding the coefficient of friction under the rivet heads and the initial tension in the shank. The splicing action of the rivet heads, in some degree, makes up for the loss of section due to rivet holes in a plate girder and, to some extent, explains the increase in effective moment of inertia of the riveted specimen when compared with the specimen with open holes.

Now, if the condition in Fig. 8 is changed by the introduction of shearing forces, *S*, the total tension in plates *A* and *B* will be $T_1 = F + S$, and in plates

---

[16] Associate Prof., Civ. Eng., Mass. Inst. of Tech., Cambridge, Mass.

C and D will be $T_2 = F - S$. If $T_2 = 0$, there will be no stress to transfer from D to B or from C to A, although the total stress to be spliced is still $2F$. It is probable that some stress will pass from B to A by following a path which involves eccentricities; but it seems that the capacity of the rivet heads as a splice for direct stress is definitely reduced by the presence of the shearing forces. Now eliminate the gap, $G\,G$, by making C continuous with A, and B continuous with D, and the condition is similar to that occurring in the flanges of a girder. It seems reasonable to conclude that under this condition, also, the presence of shear will influence the amount of direct stress passing across the hole through the rivet head and thereby will weaken the section. In fact it has been found by test[17] that a stressed rivet has a greater effect in weakening a plate than has an open hole.

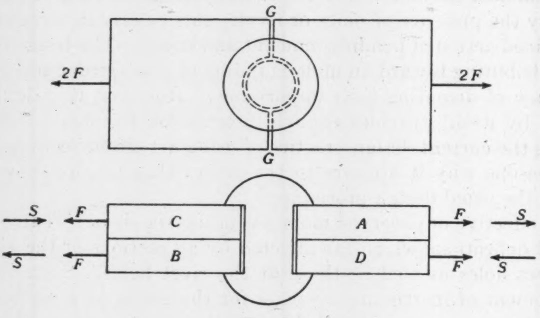

FIG. 8

Extension of the authors' conclusions to girder sections stressed simultaneously in bending and shear would not seem justified. The presence of stressed rivets in the flanges will reduce the effective moment of inertia. It is true that maximum bending moment and maximum shear do not occur at the same section except in cantilevers. However, maximum flange stress and maximum rivet shear may occur simultaneously at cross sections at the end of cover plates.

(3) The tests were made under static loading whereas, in service, girders are subjected to varying or pulsating loadings. The question of type of loading would not be involved if the rivet holes with the attending stress concentrations were not present. The effect of rivet holes differs with the two types of loading. This difference is shown by tests[18] which indicate that the tensile strength of a perforated or riveted bar under static loading is greater than that of a solid bar of the same net cross section (57,600, 59,700, and 62,300 lb per sq in. for solid, perforated, and riveted bars, respectively). However, the fatigue strength of the perforated and riveted bars is considerably less than that for the solid bar under a loading that pulsates from 2,820 lb per sq in. to the breaking stress (39,100, 29,900, and 24,300 lb per sq in. for solid,

---

[17] "Tension Tests of Large Riveted Joints," by Raymond E. Davis and Glenn B. Woodruff, Members, Am. Soc. C. E., and Harmer E. Davis, Assoc. M. Am. Soc. C. E.; discussion by W. M. Wilson, M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., October, 1939, pp. 1454 and 1462.

[18] "Gemeinschaftsversuche zur Bestimmung der Schwellzugfestigkeit voller, gelochter und genieteter Stäbe," by K. Klöppel, *Der Stahlbau*, Berlin, June 19, 1936, pp. 97–112.

perforated, and riveted bars, respectively). In other words, the influence of stress concentrations may be disregarded under static loading but it cannot be disregarded under a vibrating loading. It is true that in a properly designed new structure the primary stress will not attain a value of 24,300 lb per sq in. and the condition is not nearly so bad as this value might indicate.

The stress concentrations adjacent to the rivet holes nullify the assumption of linear stress variation used in the ordinary beam theory and thereby lead to an observed moment of inertia which, under static loading, is larger than that computed for the net section. The difference between observed and computed moments of inertia for the "B" test sections (Table 3, Columns (1) and (4)) may be explained in part by this action. Under the action of a pulsating loading the aid given by the stress concentrations is diminished or lost entirely.

(4) These tests were not intended to reveal the useful carrying capacity of the girders—that is, the yield point of the girder as a whole, or the point at which the girder deflection increases rapidly with further application of loading. This is probably the proper point to which the margin of safety should be measured. If the girder deflection is in direct proportion to the loading until the useful carrying capacity is reached, the flange-stress intensity might be used as a measure of the factor of safety. Otherwise the factor of safety must be based on applied loading.

Due to the presence of stress concentrations at the rivet holes, it is quite possible that the linear relation between girder deflection and applied loading may cease to exist shortly after the stress in the vicinity of the rivet holes exceeds the yield point. This may occur while the average flange stress is still considerably within the elastic range. On the other hand, it is also possible that this linear relation may extend to a loading exceeding that at which the average flange stress is equal to the yield point stress. It would be interesting to know the relation between loading, strain gage reading, and deflection for the specimen PT-1 which was loaded to produce a flange stress of 30 kips per sq in.

It may be quite desirable and safe to design on the basis of gross moment of inertia as recommended by the authors. The writer feels that such a procedure would evaluate actual conditions correctly for only a small percentage of cases, and that in most cases the procedure would provide an actual margin of safety which would be less than the assumed amount. However, considering the fact that secondary stresses in plate girders are likely to be small, it may be permissible to reduce the margin of safety. From this point of view the weakening effect of rivet holes would be treated as a secondary effect which would be covered by the margin of safety. Until the influence of holes and rivets in girders is established more definitely, it is the writer's belief that the customary practice of using net section should not be abandoned.

Edward Godfrey,[19] M. Am. Soc. C. E. (by letter).—Conclusion 3 is correct. It agrees with what the writer has long held to be proper in design—namely, that the neutral axis of a girder should be considered in the center of gravity of the gross cross section. Furthermore, the sentence in Conclusion 5, "design methods should be made as simple as possible," expresses what the writer has stated many times.

---

[19] Structural Engr., Pittsburgh, Pa.

The last sentence in Conclusion 1 is not clear. It reads: "The net moment of inertia, used in design with top and bottom flanges alike, should yield conservative stresses." This does not seem to comport with the trend of the paper nor the other conclusions. The authors do not seem to be advocating the use of net moment of inertia in design but rather the reverse. The trend of the paper seems to be toward justification of the practice of using the gross moment of inertia. There is no question about the safety of design that uses the net moment of inertia.

Deflection measurements and extensometer measurements do not tell anything of value about the actual, or critical, stresses of perforated flanges of a girder or of perforated plates or angles in tension. These measurements show only the average stress in the length of piece where measurement is made. The extension beside the rivet hole is only a small fraction of that in the part not perforated, although the actual unit stress beside the hole may be very much greater than in the part not perforated.

Suppose, in a girder or I-beam, there were transverse saw slits instead of rivet holes. Deflection and extensometer measurements would be practically identical, in such members, with those of solid members of the same dimensions for stresses within the elastic limit. This is because the actual stretch beside the slit is only a very small fraction of the stretch between slits in the longitudinal direction. No one will contend that the members with the saw slits will be as safe as the solid ones.

The only difference between a plate perforated with saw slits and one perforated with rivet holes, so far as safety in tension is concerned, is that the former will probably break at, or a little above, the yield point, whereas the latter may hold until the usual ultimate stress is reached. The writer has made tests where ordinary steel specimens broke just above the usual yield point of the net area beside punched holes, whereas pieces with drilled or reamed holes broke at the usual ultimate stress.

The writer is quite out of agreement with Conclusion 5. It is a damaging admission to say that stresses as ordinarily specified for structural work result in unit stresses "reaching" the yield point of the steel as the unit stress in the gross section "approaches" that specified. This can mean nothing else but that, when the allowed unit stress on the gross section is reached, the actual unit stress beside rivet holes exceeds the yield point. The argument has been that rivets pinch the metal together, and the resulting friction under the head compensates for the loss of tension area in the perforated plates.

To say that nothing can be done to avert the condition is to forget that rational methods of design can be reverted to that treat a perforated plate as just what it is—namely, a plate that is weakened by the holes punched in it, good only for its net section in tension.

The method once universally used of finding the effective depth of a plate girder and proportioning the compression flange for its gross area and the tension flange for its net area is eminently rational and results in design to which exception cannot be taken from any standpoint.

The authors state, "Once a ductile material is strained beyond the yield point and the load is released, residual stresses are set up which will be beneficial in resisting the next applied load." This does not agree with abundant experience in the use of chains and axles. Chains will stand loads beyond their yield point for so long; then they are likely to break. Chain users know this, and they anneal their chains at times. Axles stand, repeatedly, the load that may finally break them. There is such a thing as fatigue, and frequently breaks occur with a comparatively small number of repetitions (not up in the hundreds of thousands or any such number).

Some years ago, in Pittsburgh, Pa., a wrought-iron plate girder broke apart in the tension flange and dropped the locomotive that it had doubtless carried many times. The flange plates broke sharply, very evidently from fatigue.

The rule that designs a plate girder for gross section in the tension flange may result (where thick metal and many cover plates are used) in 4 or 5 sq in. of metal punched away in one hole. This represents a stress of 70 to 90 kips being imposed on friction under the head of a single rivet, and that rivet might be loose.

Plate-girder design needs careful scrutinizing from a rational standpoint.

WALTER H. WEISKOPF,[20] M. AM. SOC. C. E. (by letter).—The profession is indebted to the authors for an investigation of an important feature of structural engineering. For many years holes have been deducted in computing the strength of plate girders as a matter of routine.

With the authors' measurements there is little room for dispute. When one considers that the net section extends over such a small length of girder as compared to the length between the holes, it is not surprising that the holes, whether open or filled by bolts or rivets, have small effect on deflections. Engineers have recognized this for many years and have generally used the gross moment of inertia when computing deflections or stiffness coefficients for use in designing statically indeterminate structures. Likewise, it is obvious that the holes have a negligible effect in shifting the neutral axis from the center of gravity of the section. For the same reason, also, a practically negligible increase in flange stress due to the holes was discovered by the method the authors employed in measuring such flange stresses. Since this stress was computed from the strain in a 10-in. length of flange, it was obviously determined by the average of the strains in many differential lengths of gross section and a much smaller number of differential lengths of net section. The method thus failed to detect the very high concentrations of stress around the holes well known to investigators of this subject and mentioned, but not quantitatively given, by the authors in Fig. 5.

With the authors' conclusions, however, there is room for very clear disagreement. The authors state that nothing can be done to prevent the high stress concentrations around holes. Actually, these can be eliminated very simply in all but girders with very large flanges by eliminating the flange rivets, either by using welded cover plates or by employing a flange composed of a split beam tee and two angles.[21]

---

[20] Cons. Engr. (Weiskopf & Pickworth), New York, N. Y.

The writer also emphatically disagrees with the authors' recommendation of using the gross moment of inertia with the usual fiber stress. Frequently, the area of the holes is very considerable as compared with the remaining flange section. In heavy cramped work a common flange consists of 8-in. by 8-in. angles and 17-in. or 18-in. cover plates, with four lines of rivets through the covers. Often the stagger is so small that the net section traverses all four rivets so that the cover plate area is as much as 22% rivet holes. This is far too important an item to treat lightly, and it is improper engineering to dismiss the high stresses around these holes with the casual remark "and nothing can be done to prevent them."

The purpose of strength computations is to provide a safe and reasonably efficient design. An efficient design is one in which all parts of the structure have about the same margin of safety or safety factor. It is obvious that a riveted girder with high stress concentrations at the holes is definitely inferior to a plain rolled beam or to a girder of another type which has no such holes; and a balanced design requires that this feature be given due consideration.

One way of compensating for the detrimental effect of the holes is the practice, extensively used, of designing by the net section. Another simpler, and perhaps more practical, method which has been suggested is to base the design on the gross moment of inertia but to reduce the fiber stress according to some function of the ratio of net to gross flange.

C. D. Williams,[22] Esq. (by letter).—Some interesting data are offered in this paper, although the conclusions may not be concurred in by all engineers. It should be noted that the stress intensities reported by the authors are based on average stresses as computed from the strains on 10-in. gage lengths. This set-up, of course, does not give the maximum stress values—a fact that is recognized by the authors.

It should be proper at this point to make some comparisons of their results with the results that would be expected when the stresses are computed according to the commonly accepted practice of deducting rivet holes in the tension flange.

The stretch of any finite length under stress is equal to the unit stress times the length, divided by the modulus of elasticity. When there are two or more unit stress intensities in the length considered, the stretch may be found by use of the average stress per unit length. If there were no reductions in area throughout the length the average stress and the maximum stress would ordinarily be equal. However, when there are local reductions in area, the average stress producing elongation will be increased thereby. The reduction in area and the length over which it occurs are both factors in the increase of stretch due to a given force since they influence the average stress over the finite length considered. In other words, the stretch of a finite length due to load is inversely proportional to the volume taking stress.

[21] "A Comparative Analysis of Plate Girders," by Walter H. Weiskopf and John W. Pickworth, Members, Am. Soc. C. E., *Civil Engineering*, November, 1934, p. 585.

[22] Associate Prof., Head of Dept. of Structural Eng., Fenn College, Cleveland, Ohio.

In considering the effect of a local reduction in area upon the deformation of a finite length longer than that which is reduced comparison may then be made between the reduced and unreduced volumes for the finite length.

* Or, the equivalent average area deduction.

Table 7 contains certain properties of the girders of series C and D taken from the details of the paper. These are the series that had holes in the tension flanges. Values in Column (5) are obtained by deducting two $\frac{3}{4}$-in. holes from the horizontal legs of angles and cover plates and one-half of a $\frac{3}{4}$-in. hole through the two vertical legs. The volume deduction shown in Column (6) is computed for sections in Table 7(*a*) as the volume of metal removed by two $\frac{3}{4}$-in. holes through the horizontal legs and cover plates and one $\frac{3}{4}$-in. hole through the two vertical legs; for sections in Table 7(*b*) the holes in the vertical legs are spaced 5 in.; therefore only one-half of the volume of these holes is included.

The results listed in Columns (7) and (8) are the deductions in volume and the percentage deductions in volume due to rivet holes. Column (9) is computed from Columns (1) and (2) of Table 3 and is the percentage by which the values of Column (1) are less than those of Column (2). Column (9), then, is the percentage of increase in the average stress which the authors found due to rivet holes. Column (8) is the percentage reduction of volume in the gage length due to rivet holes; or, inversely, it is the percentage increase in average unit stress.

The comparison of the values in Columns (8) and (9) is remarkable, especially in view of the authors' claim to an accuracy of only within about 1.5 per cent.

The writer would like to suggest the following conclusions on the basis of the data submitted by the authors:

1. In view of the fact that the average stress intensities as found by measuring strains on 10-in. gage lines check so closely the average values found by deducting rivet holes from the tension flanges, it would seem to follow that the maximum intensities of stress are more correctly given by use of the net moment of inertia than by the gross moment of inertia.
2. Since the measurement of strains for the purpose of locating the neutral axis was made on 10-in. gage lines and did not register maximum intensities of stress, local deviations of the neutral axis could be present without detection. Since the measurements all indicate that the average location of the neutral axis is moved up by drilling holes in the bottom flange, there seems ample justification of the usual procedure of considering the neutral axis to be at the gravity axis of the net section.
3. Since the average location of the neutral axis is only slightly above the gravity axis of the gross section this axis may be used satisfactorily for the computation of the deflection of the girder, as may the moment of inertia of the gross section; but deflection due to average stress and maximum stress intensity should not be confused.
4. Since the use of the gross section in computing stress intensity is obviously opposed to conservatism, and since there are likely to be stress concentrations in the region of rivets not affecting the longitudinal deformations, it seems proper to use the net moment of inertia in the design of girders until a more conservative and exact method is found.

Alvin B. Auerbach,[23] Jun. Am. Soc. C. E. (by letter).—To paraphrase an utterance of Hardy Cross, M. Am. Soc. C. E., a structure, not being cognizant of its designer's assumptions, always deforms in accordance to the laws of geometry and statics.[24] Both common design practice and experience agree that the deflections of a girder are a function of the gross section. Hence a suitable design method should:

1. Be based upon the deformation of the girder and therefore on the gross section;
2. Yield maximum computed stresses in consonance with the underlying assumptions of the specifications governing the design;
3. Be capable of being visualized by the user; and
4. Be adaptable to girders of unusual shape or section.

Under "Conclusions" the authors state: "It is believed that the data from these tests point to the acceptability of the gross moment of inertia for design purposes." The writer proposes to show that it is possible to analyze a structure so as to yield higher design stresses which are still in consonance with the average measured stress found by the authors.

For example, a method of design which meets Conditions 1 to 4 is the one utilizing the ratio of the equivalent net flange area to the gross. It was used in the U. S. Engineer Office, Rock Island (Ill.) District, for the design of the plate girders having a concave lower flange, and unsymmetrical sections. These girders were the service bridge spanning the movable gate openings on the Mississippi River dams. Using the relationship derived in standard texts on design of plate girders, the equivalent gross area is expressed by:

---

[23] 1st Lieut., Corps of Engrs., U. S. Army, Fort Du Pont, Del.

[24] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1373.

$$A_e = A_f + \frac{A_w}{6} \quad \text{.......................} \quad (7a)$$

and the equivalent net area by:

$$A_e' = A_f' + \frac{A_w}{\dfrac{6\,p}{p - r}} \quad \text{.......................} \quad (7b)$$

in which A_f and A_f' are the gross and net flange areas, respectively; A_w is the gross area of the web; p is the vertical pitch of rivets in the web (as in stiffeners); and r is the diameter of the rivet holes.

Accordingly, in compression,

$$s = \frac{M\,c}{I_{(\text{gross})}} \quad \text{.......................} \quad (8a)$$

and, in tension,

$$s = \frac{M\,c'}{I_{(\text{gross})}} \times \frac{A_e}{A_e'} \quad \text{.......................} \quad (8b)$$

TABLE 8.—EQUIVALENT FLANGE AREAS, IN SQUARE INCHES

Section	Dimensions, in inches	Equivalent Areas	
		Gross, A	Net, A'
Web	12 by 5/16	0.63	0.63
Angles	2½ by 2½ by ¼	2.38	2.04
Cover plate	6 by ¼	1.50	1.16
Cover plate	8 by ¼	2.00	1.66
Totals	....	6.51	5.49

Using the data supplied by the authors, for girder D-3, the areas are as shown in Table 8. From Column (9), Table 3, the computed stress for the gross section is 19.1 kips per sq in.; the maximum tensile stress would be $19.1 \times \frac{6.51}{5.49} = 22.7$ kips per sq in.; and thus the average tensile stress $\frac{22.7 + 19.1}{2} = 20.9$ kips per sq in. This is in fairly good agreement with the measured average tensile stress of 20.2 kips per sq in.

The results obtained by this method, although numerically slightly higher than other methods, better meet the desired conditions. The underlying reasoning is simple; it is easily adaptable to unusual girders. Also it does not encroach on the much abused factor of safety, which, already carrying allowances for defects of material, imperfections of workmanship, secondary stresses, local stress concentrations, and other intangibles, needs some protection lest it become the great unknown. It may be interesting to note that in military design of bridges in war time the factor of safety based on existing civil practice is to be flatly reduced by 20% for steel structures.

Most present-day specifications utilize design stresses based on double net areas, with results that are almost identical with the foregoing; but these specifications are not feasible for unsymmetrical girder sections. If stresses are to be raised, let the design stresses be increased openly rather than permit the increase to be hidden in illogical analysis.

JONATHAN JONES,[25] M. AM. SOC. C. E. (by letter).—When the Committee on Specifications of the American Institute of Steel Construction determined (1936) to adopt gross moment of inertia for the design of plate girders in building construction, it did so on the basis of a reasoning, satisfactory to its members, with respect to actual unit stresses on sections through rivet holes. That reasoning may be summarized somewhat as follows:

(1) A statically-loaded plate girder can scarcely be made to fail in the tension flange; the compression flange and the web usually determine the capacity.

(2) All manner of things have happened to overloaded crane girders in mill buildings, but not to the tension flanges.

(3) In normal, simple-span girders the flange area removed by rivet holes is less than 15%. The rivets are practically always machine-driven, and they induce a friction in the heads which carries part of the stress.

(4) If occasional rivets are loose, and the friction in Item 3 is nonexistent, the most severe stress that can occur is somewhat less than 23,000 lb per sq in., and the designer would rather have 23,000 in a plate girder flange than 20,000 in many other elements of a building.

(5) Flanges that are "chopped up" by closer spacing of rivets, on account of heavy shears to be developed in short distances, should not be required to carry still greater net stresses due to excessive reduction in area; and therefore a maximum exempted reduction of 15% resulting from a "chain" of holes was established.

(6) Holes filled with bolts, pins, or countersunk rivets have less hope of being assisted by friction, and should be deducted.

The specification clause[26] was drafted to authorize the use of gross sections, subject to the foregoing implied limitations. It was submitted to a number of engineers and met, not with unanimous, but with general, approval.

The desire for a research project arose after the specification had been thus drafted and adopted; its purpose was not to convince the Specification Committee, which had already acted, but to reconcile, if possible, some objectors to what the Specification Committee had done. No one expected to show, by a research project, that there are not peak points of high unit stress around rivet holes; or that, if a tension flange could be made to rupture, it would rupture elsewhere than through a hole. What could be shown, and has been shown, is that

(*a*) Exemption of rivet hole deductions to as much as 15% of the gross flange area is conservative (rivet hole deduction in test specimens 18.0% minimum and 23.4% maximum);

[26] A.I.S.C. Specification for Design, Fabrication and Erection of Structural Steel for Buildings, Section 19*a*, 1936; also A.I.S.C. Manual on "Steel Construction," Third Edition, October, 1937, p. 272.

(*b*) Drilling holes in a solid flange increases the average unit stress over that in the solid material; but

(*c*) Bolts or rivets in these holes will go a long way toward reducing this average unit stress to what it was in the solid material;

(*d*) Bolts performed about as well as rivets in this respect, but these were tightened, of course, with considerable care.

The research project has been successful in demonstrating all that was hoped for. It has not disposed of the spots of overstress backed up by lower-stressed material, which were not the subject of this particular study. Engineers still may be divided into those who believe that the gross-section-modulus specification represents a sound attitude, and those who believe otherwise. For the former group, including the A.I.S.C. Specification Committee, it may be said that, as raw materials tend toward scarcity and high cost, it will be more and more necessary to dispense with inherited extravagances which a practical consideration of probable behavior may serve to eliminate.

R. L. Moore,[27] Assoc. M. Am. Soc. C. E. (by letter).—Certain phases of plate-girder behavior have always been open to question, namely: (1) What are the effects of rivet holes upon the behavior of a plate girder; and (2) what allowance should be made for their effects in design? As is generally recognized, specifications are not in agreement on the latter question. In some cases plate girders are proportioned on the basis of the gross section;[28] in others the net section of both tension and compression flanges is used in computing tensile stresses, whereas the corresponding compressive stresses are based on the gross section.[29]

Apparently, the logic behind the use of net sections in proportioning plate girders is that such a procedure provides some allowance for a reduction in strength resulting from rivet holes in the flanges. Little or no information, either from experience or tests, is available, however, to indicate how essential such a procedure may be. It is generally assumed, as stated in the paper, that bending deflections may be computed with reasonable accuracy, using moments of inertia based on gross sections. This view is supported by Table 3 in which the differences between observed effective moments of inertia and those computed on the basis of gross sections averaged only 3% in the case of specimen PT-1 and 6% for specimen PT-2, with the maximum individual differences amounting to only about double the foregoing percentages in each case. If moments of inertia for gross sections are satisfactory for computing deflections, it would seem to follow that they are also satisfactory for computing average flange stresses, since deflections are merely a reflection of the strains corresponding to such average stresses. The computation of stresses on the basis of net section may result in increases of from 10% to 15% over those obtained using gross sections; but such increases are of little significance in view of the stress concentrations of from two to three times the average actually produced in the flanges by the rivet holes. As long as questions concerning fatigue strength under repeated loadings are not involved, and average rather than maximum values of flange stress are used as a basis for design, the use of gross sections seems satisfactory.

[29] See A.R.E.A. Specifications for Steel Railway Bridges, Art. 426, 1938.

The authors state that their tests were planned to discover, if possible, how much the flange stresses in plate girders are affected by the rivet holes in the flanges. Unfortunately, they have presented no data pertaining to the actual stress distribution in the flanges; neither have they given any information to indicate what effect the stress concentrations at the rivet holes might have on the ultimate strength of the girders. The fact that some of the 10-in. gage lines used in their tests were located in line with the holes in the flanges means that the changes in length measured included hole distortions as well as strains in the material. Obviously, such deformations have no bearing upon the actual stress distribution, although they would be expected to be consistent with the strains corresponding to the measured deflections.

The observed stresses shown in Table 3 are in good agreement with the computed values based on either the observed effective moments of inertia or those based on gross sections, since there is little difference between these quantities. Although the stresses measured in the tension flanges were consistently higher than those found in the compression flanges, the agreement between measured and computed values based on net sections was not as satisfactory as that found for gross sections. The discrepancy would have been even greater if the authors had made reductions in area from both tension and compression flanges in computing net sections, which is the procedure suggested by the measurements made of the position of the neutral axis. In compression flanges, where the holes are filled tightly by rivets or by body-bound bolts, there may be some justification for assuming these flanges to be solid and making deductions from the tension side only. Where there are open holes in both tension and compression flanges, however (as in the authors' series B tests), or where the holes are filled with loose fitting bolts (as in the series C tests), there would seem to be no reason for not making deductions in area from both flanges if the question of net section is really a significant one.

In order to corroborate the authors' general conclusion that the gross-section method is satisfactory for computing plate-girder stresses in most cases, a few experimental data from a test on an aluminum-alloy plate girder have been included in this discussion. Fig. 9 shows the measured stress distribution in the extreme fibers of the web of a girder section subjected to pure bending. The stresses shown correspond to strains obtained by means of tensometers on ½-in. gage lengths midway between, and directly over, the flange rivets. The interesting fact about these data is that the stresses between rivets are higher than on the net section through the center of the rivets. Although this behavior is consistent with the elastic theory regarding the effect of stress concentrations produced by holes near the edge of a wide plate, it is contrary to the result expected when the net-section method is used to determine stresses in design. The stresses measured on the tension side of the web were consistently higher than those found on the compression side (as was also found in the authors' tests), but the maximum values in both cases are reasonably consistent with the stresses computed on the basis of the gross section. The use of the net section for the tension flange would increase the computed stresses in that flange by about 11%, but would give a greater difference between measured and computed stresses than that indicated in Fig. 9.

FIG. 9.—MEASURED STRESS DISTRIBUTION IN WEB OF ALUMINUM ALLOY PLATE-GIRDER SECTION SUBJECTED TO PURE BENDING

The authors propose a formula for computing effective moments of inertia of plate girders which involves not only the rivet pitch and hole diameter, but an experimentally determined constant which they have evaluated within certain limits. Such a refinement in the computation of stresses and deflections scarcely seems justified from the data given in the paper. One objection that might be raised to such a procedure is that no consideration is given to the possible lack of integral action between the elements of a plate girder. For some proportions it appears that this factor may be of even more significance than the effect of rivet holes. The various parts of a plate girder function, of course, through their connections. Load can be transmitted from the web to the flange angles and cover plates only through the action of the rivets, which involves deformations and slip. It would have been of interest in this connection if the authors had included some of the strains measured in the web and flanges of the test girders. The two types of data did not indicate the same position of the neutral axis, as shown in Table 1. It is conceivable that they might also have thrown some light on the question of integral action.

J. M. GARRELTS,[30] ASSOC. M. AM. SOC. C. E., AND I. E. MADSEN,[31] JUN. AM. SOC. C. E. (by letter).—There is some difference of opinion as to the behavior of the elements of a plate-girder beam under load. With the adoption of increased unit design stresses, it becomes important for engineers to examine some of the fundamental assumptions that have been used for designing such beams.

---

[30] Associate Prof., Civ. Eng., Columbia Univ., New York, N. Y.

[31] Asst. Research Engr., Fritz Eng. Laboratory, Lehigh Univ., Bethlehem, Pa.

The authors' research represents an excellent attempt to learn more about the plate-girder beam by observing the action of test girders under load. The questions relating to the position of the neutral axis and to the moment of inertia of the beam are important and warrant investigation because they are uncertain quantities.

The writers are of the opinion that for a beam with open holes in both flanges (similar to series B in the tests) the neutral axis will remain at the center line for some range of loads, perhaps up to the working load. Since the stress-strain relation is taken to be the same in compression as in tension, the deformations would be equal in the two flanges as long as the action is in the elastic range of the material. Thus, until plastic deformation occurs on the entire flange cross section at an open hole, there is no reason for a shift of the neutral axis. The effect of stress concentrations at the edges of the holes would not affect this action appreciably.

When there are bolts or rivets in the holes, the deformations in the two flanges may also be essentially equal for some range of loads. In a region of pure moment, this action will depend on how well the rivets fill the holes, and on the friction forces developed by the rivet heads. If the rivets or bolts fill the holes sufficiently well to offer resistance to deformation of the flange materials, the transmission of forces across the net section will be of a different nature in the two flanges and will produce an unsymmetrical effect. The friction forces acting on the rivet heads will generally develop some tensile or compressive stresses in the rivet heads, thus providing some splicing action at that section.

The writers are in doubt as to what is meant by the statement (see heading "Conclusions"): "It is believed that the data from these tests point to the acceptability of the gross moment of inertia for design purposes." Do the authors refer to design computations for deflection, or for stress? If the latter is meant, the writers do not agree. A consideration of statics will show that the average stress on a cross section through a rivet hole must be larger than that on a gross cross section. In addition to the expected variation of stress due to stress concentration adjacent to the holes, strains measured on 0.5-in. gage lengths by the writers show a higher average unit strain at a cross section through a rivet hole than at a cross section taken between rivet holes. The 10-in. Whittemore strain gage, used in the authors' tests, measures the over-all average strain for all cross sections included in the 10-in. length, but does not give the average strain at the minimum cross section.

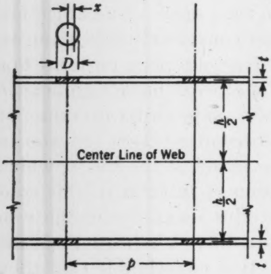

FIG. 10

It seems inconsistent to use the gross moment of inertia for proportioning the parts of a girder according to allowable stresses and an "effective" moment of inertia for computing deflections. The writers are of the opinion that an "effective" moment of inertia is an unnecessary refinement, because it represents the action that occurs only for the case of open holes, or for that in which the bolts or rivets do not fill the holes and therefore offer no resistance to deformation of the flange materials. If this procedure of using the weighted average of the moments of inertia for gross sections and sections through the holes is to be used, however, an average moment of inertia per unit of length of the girder can be determined by the following formula (see Fig. 10):

$$I_a = I_G - \frac{1}{p}\int_{-D/2}^{D/2}\left(2\sqrt{\frac{D^2}{4} - x^2}\right) t\, N \left(\frac{h}{2}\right)^2 dx$$

$$= I_G - (N\, t\, D)\left(\frac{h}{2}\right)^2 \frac{\pi}{4} \times \frac{D}{p} = I_G - I_H \times \frac{\pi}{4} \times \frac{D}{p} \ldots\ldots\ldots (9)$$

in which I_a = average moment of inertia per unit of length; N = number of rivet holes at cross section; D = diameter of rivet holes; p = rivet pitch; and I_H = the moment of inertia of the area of the holes, taken at the diameter of the holes.

Assuming

$$m = \frac{I_a}{I_G} = 1 - \frac{I_H}{I_G} \times \frac{D}{p} \times \frac{\pi}{4} \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

values of m are shown in Table 9.

TABLE 9.—COMPARISON OF VALUES OF $m = \frac{I_a}{I_G}$

Section	Value of m by experiment	Computed value of m	Percentage deviation	Value of m by experiment	Computed value of m	Percentage deviation
C1	0.970	0.971	+0.1	0.928	0.942	+1.5
C2	0.970	0.973	+0.3	0.936	0.945	+1.0
C3	0.962	0.975	+1.3	0.916	0.951	+3.8
C4	....	....	....	0.930	0.951	+2.3
D3	0.980	0.975	−0.5	....	....	....

The computed values of m check fairly well with the experimental values. However, the experimental values are not a true representation of $\frac{I_E}{I_G}$. This is readily seen when the method for determining m is considered. The value of m was computed as the ratio of the loads required to produce equal deflections for a given girder section and the corresponding section of series A. Since there were rivet holes in the vertical legs of the flange angles of the series A sections, the experimental values for m represent a comparison of the effective moment of inertia (I) for series B, C, and D with the effective I of series A.

The value of the factor k in the authors' equations is $\frac{\pi}{4}$, the same as the coefficient in Equations (9) and (10) for I_a. This quantity is a shape factor and depends only on the shape of the holes.

The exact behavior of the elements in a plate girder is unpredictable because of the uncertainty of the action of the rivets; but tests such as those that the authors report will aid in a correlation of the analysis with the possible structural action for which the girder should be designed.

FRANCIS P. WITMER,[32] M. AM. SOC. C. E. (by letter).—The interesting experiment reported in this paper has verified, satisfactorily, the general understanding among structural engineers that deflections of a plate girder are in practical accord with the gross, rather than with the net, moment of inertia. A similar relation, however, cannot be accepted so readily as regards maximum effective unit stress in the tensile flange. In the investigation of old plate girder structures whose sufficiency for modern loading was in question, the writer has found it convenient to use the method described below for the determination of these tensile unit stresses. Assume the girder to deflect in accordance with its gross moment of inertia. Since the section is symmetrical, this places the neutral axis at the center of the web plate, and also presupposes that the rivets hold the parts together with sufficient force to prevent slip and, therefore, to develop stresses which are in accord with bending theory.

If c is the distance from the neutral axis to the extreme fiber, the maximum unit stress on the gross section will be $s = \frac{M\,c}{I}$. If the distance from the neutral axis to any flange rivet line (either through the web or through cover plates) is y, the unit stress on the gross section at this line of rivets will be $s' = s\,\frac{y}{c}$.

This unit stress will occur in the part of the flange between rivets. A rivet hole will cut from the flange section an area equal to $2\,D\,t$, in which D is the diameter of the hole and t is the thickness of flange angle, or, for cover-plate rivets, the combined thickness of angle and cover plates for two lines of rivets.

The rivet hole may now be regarded as cutting from the section an area whose total stress equals $s'\,(2\,D\,t)$ and causing this stress to be detoured around the rivet and ultimately divided up over the entire net section of the flange. If A represents this net section, a unit stress of $\frac{s'\,(2\,D\,t)}{A}$ will be added to each unit stress in the gross flange section between rivets. Adding this increment to the maximum extreme fiber stress, s, in the gross section, will give the maximum tensile unit stress in the section.

This method of procedure is inconsistent in that it assumes the gripping action of the rivets to be sufficient to cause a distribution of fiber stresses between rivets which is proportional to the distance from the neutral axis; but it does not consider the frictional force under the rivet head as sufficient to prevent the increment of stress, due to the flange material cut out by the rivet hole, from being carried around the rivet. The results, however, are believed to be more nearly correct than those by either the method of net moment of inertia or that of net flange area. For a girder without cover plates, the result will usually be nearly the same as by the net flange area method; but if there are cover plates, it will generally be somewhat less than this value.

---

[32] Director, Civ. Eng., Univ. of Pennsylvania, Philadelphia, Pa.

A. W. FISCHER,[33] ESQ. (by letter).—The experiments and results reported in this paper were conducted with great care and refinement.

According to all the tests, the neutral axis remained fairly close in position to the center of gravity of the gross section; and this seems reasonable because the rivet holes in the tension flange do not remove much metal as compared to the entire volume of the tension flange. With a 5-in. pitch there is slightly less shift than at a 2.5-in. pitch, and that is as it should be; and, for average conditions, the writer will agree that, for the deflection of a riveted plate girder, it will be satisfactory to assume the neutral axis at the center of gravity of the gross section, and to use the gross moment of inertia. The computed deflection will then be a trifle less than it really is by experiment; but the variation will be small, and may never be more than 3% in error.

A riveted plate girder acts similarly to a truss. Every engineer will deduct the rivet holes in the tension flange of a steel truss, and for that reason it seems that rivet holes should be deducted from the tension flange of a riveted plate girder to ascertain the true stresses.

The authors failed to secure a true measure of the stress in the net section, for the tension flange, because of their testing procedure. The true stress at the section where the rivets occur cannot be computed from the readings of a 10-in. gage length. Only an average stress can be computed; and this average will be less than the actual at the rivet section. Furthermore, it is impossible to determine the true tensile stress at the section of a line of rivets if round holes are used. The only solution is to use slotted holes at the section where the stretch is to be measured, the slotted part being, say, 1 in. long, and the width being the diameter of the rivet hole. If the slotted part is actually 1 in. long, if a gage length of 1 in. is used, and if the average of several positions across the net area of the tension flange is used, then from such a test the average of the calculated results will represent the true stress at that section as closely as an experiment can be made to determine it. Tests should first be performed using slotted holes at the net section tested, and then the load should be removed. After the load is removed rivets shall be placed in the slotted holes and tested again to ascertain if the grip of rivet heads change the stresses.

The plate girder tested by the authors was rather shallow; a representative girder of reasonable depth should be tested, and several cover plates should be used so that the effect of rivet-head grip on the outer cover plate and the outstanding leg of the angles at the net section will be reduced to an average minimum.

One item that is not clear to the writer is just how the 10-in. gage length was converted to the true stretch of the bottom tension flange. A slight curvature in the beam seems to indicate that the actual gage length measured was the chord length and not the true arc length. It seems that the shorter the gage length the more definitely the true stretch can be ascertained.

The I_E-value as given in Equation (5) is too large. Before it is adopted, additional tests should be performed on representative girders, reasonably deep, and including several cover plates. The writer will agree that the pitch of the rivets in the tension flange should be used in the general equation so as to take care of the slight shift of the neutral axis, and the writer would not use a greater value for I_E than the following for the design of a riveted plate girder:

---

[33] Asst. Structural Engr., Construction Service, Veterans Administration, Washington, D. C.

$$I_E = \frac{p\, I_N}{p + \left(\frac{I_G}{I_N}\right) - 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

in which I_N is equal to I_G minus the moment of inertia of the rivet holes in the tension flange only, about the gravity axis of the gross section. The section modulus then equals I_E divided by the distance from the gravity axis of the gross section to the extreme tension fiber.

J. R. SHANK,[34] M. AM. SOC. C. E. (by letter).—Few engineers would think of using the net-section moment of inertia of a plate girder for computing the deflection for the reason that it is representative of so little of the length. The gross-section moment of inertia represents much more of it. A moment of inertia proportioned between these two is more likely than either of them to be the proper one to use. The deflection data of this paper afford excellent material for making a study of the proper basis for this proportioning. If the addition of holes in the tension flange causes an increase in the deflection, it is apparent that the angular movement due to the bending of that part at the holes is no longer the same as if no holes were present and the use of the gross moment of inertia is therefore only an approximation. The deflection may be computed in detail for gross section and net section progressively, as they come, or fairly accurately from gross and net sections in proportion to the parts of the lengths taken by the two. If the deflections given in this paper are equal to the deflections so computed, the conclusion must be drawn that the angular movement as computed from the net moment of inertia obtains at the regions containing holes and the fiber deformations and stresses are different from those at no holes.

Table 10 is an attempt to show the effect of the holes on the reduction of the load-carrying characteristics as illustrated by the moments of inertia. For a given deflection the moments of inertia are directly proportional to the loads carried. Columns (1) and (5) of Table 10 are taken directly from Columns (3) and (1) of Table 3. The percentage reductions are all computed from the A-value for each group. Column (3) is not found in the original paper. For PT-1 specimens having $\frac{11}{16}$-in. holes, spaced 5 in. apart, 13.7% of the entire length is at holes and 86.3% at no holes, or at gross section. Accordingly it is assumed that 86.3% of the girder has a moment of inertia of, say, 178.5 for specimens without cover plates, and 13.7% has a moment of inertia of 164.3. For convenience, the holes are considered to be $\frac{11}{16}$ in. square; thus:

$$178.5 \times 0.863 = 154.0$$
$$164.3 \times \frac{0.137}{1.000} + \frac{22.5}{176.5}$$

The effective moment of inertia for computing deflection or the proportional moment of inertia, as designated herein, is then 176.5. This procedure is substantially the same as that which would be used for computing the deflection of a girder having two different moments of inertia when the number of alternations of the two are allowed to increase toward infinity.

D-3	430.0	9.8	471	1.2	480.5	2.7	433.2	9.8	467	2.7	460.0	8.0

The percentage reductions shown in Column (2), Table 10, are those which would be expected if the holes ran in the form of slots for the full length of the girder. If the holes had no effect on the deflection, these percentages would all be zero. There are the two extremes. If the stresses at the holes are what would be expected from the net-section calculations, the reductions would be as shown in Column (4), Table 10. Column (6) shows the percentage reductions for the observed moments of inertia. The moments of inertia shown in Column (5) are larger than those in Column (1), and a reference to the paper shows them to be generally somewhat smaller than the gross section values of Column (2), Table 3. These differences are immaterial inasmuch as the comparisons are by percentages.

The material in the number 1 group, A-1, B-1, and C-1, is the most valuable since the A-values were not taken from girders where clamps were relied upon to develop the horizontal shear as was the case for the others. In all cases except one the effect of the holes was greater than would be expected from ordinary net-section calculations, taking into account the proportionate length occupied by the reduced section. The stiffening effects due to bolts and rivets are shown clearly. The discrepancies between the values of Columns (6) and (4), Table 10, are greater for the closely spaced holes. It appears that the holes have an effect over a length greater than their diameters and that the substitution of square holes for round holes is not nearly enough to cover this condition. In the cases of the close spacings these effects apparently met or overlapped.

The conclusion seems to be clear that the net-section method for the calculation of tensile fiber stresses indicates the actual situation much more accurately than the gross-section moment of inertia; and if designing plate girders by the gross-section moment of inertia is to be continued, it should be recognized clearly that considerably greater stresses occur at the rivet holes in the tension flange than the calculations indicate and that this fact must be taken into account when specifying allowable unit stresses.

HAROLD D. HUSSEY,[35] M. AM. SOC. C. E. (by letter).—The need of more tests of plate girders is emphasized in this paper. The tests reported were planned with care and were skilfully executed, and the writer believes that the authors' conclusions will be verified by further experimental work.

Under "Flange Stress" the authors state that the stress in the compression flange is greatest for open holes, and that it gradually approaches the computed value as the method of holding the flange together is changed from clamps, to bolts, and to rivets. The authors add that a corresponding decrease is not shown for tension flange, indicating that bolts and rivets tend to relieve the stress in the compression flange. The observed results in Column (6), Table 3, indicate that bolts and rivets tend to relieve the stress in the tension as well as the compression flange. This seems to offer evidence that the gripping action of rivets produces an appreciable reduction in the theoretical stress concentration at the sides of open holes in the flanges. Such stress concentrations may be as much as three times the gross unit stress, which indicates that they will reach the yield point of the material before the working stress is developed. It is significant that when the two girders were tested to 30 kips per sq in. there was no indication of permanent set. This is contrary to what one would expect. The fact that no set was produced is evidence of the relieving action of rivets.

The most important conclusion reached by the authors is that plate girders may be designed acceptably by the use of the gross moment of inertia. The most common consideration of this question has been on the basis of gross sections versus net sections of a tension member, when it should have been directed to the action of the plate girder.

A plate girder has one flange in tension and one flange in compression. The strength of the compression flange is determined by its resistance to buckling. It has long been known that, under static loads, the compression flange of a symmetrical girder will fail long before the tension flange has reached its ultimate strength. It has also long been known that, under static loads, it is practically impossible to make a girder fail in the tension flange, while the compression flange is still intact. This was well demonstrated in tests of plate girders which are summarized in Table 11.

These tests were made at the Ambridge, Pa., plant of the American Bridge Company in 1910. The girders were 30½ in. deep, back to back of flange angles; 28 ft long, center to center of bearings; and were made in the following general classes: Class A girders were symmetrical, without cover plates; class B girders were unsymmetrical, without cover plates, the compression flanges being heavier than the tension flanges; class C girders were symmetrical, with cover plates; class D girders were unsymmetrical, with cover plates, the compression flanges being heavier than the tension flanges; and the two class E girders were extremely unbalanced, with two angles only in the tension flanges and cover-plated compression flanges which were more than twice as heavy as the tension flanges.

---

[35] Designing Engr., Am. Bridge Co., New York, N. Y.

Load was applied to the girders at the third points of the span, through bearing blocks on the compression flanges. The two ends of the girders were held against lateral movement. The unsupported length of the compression flanges, therefore, was equal to the length of the girders except for such support as was supplied at the load points.

All of these girders failed in the same manner—that is, by buckling of the compression flanges at theoretical unit stresses which averaged 9% above the yield point. This was accompanied, in some cases, by buckling of the web plate. In only one case (Girder G11) was there failure of the tension flange. It is evident that the tension and compression unit stresses should be alike for symmetrical girders, when they are based on gross moment of inertia. The tension stress, on the basis of net moment of inertia, was somewhat higher (10% for the girders without cover plates and 20% for those with cover plates). The maximum tension stresses were still less than the ultimate—in the symmetrical girders these stresses varied from 73% to 81% of the ultimate.

Making the girders unsymmetrical resulted in an increase in the tension unit stress at failure without any appreciable change in the compression unit stress (in comparison with the yield point). These girders continued to fail by buckling of the compression flange or failure of the web plate until the dissymmetry reached the extreme values shown in girders G11 and G13, where the compression flanges were more than twice as heavy as the tension flanges. Girder G11 showed a maximum net tension stress of 105% of the ultimate tensile strength. As stated, this was the only girder in the series that was reported to have shown signs of failure in the tension flange. The report of this failure states, "Top (compression) flange and cover plates buckled and deflected downward. Complete failure of top and bottom flanges and web between loads."[36] Even in this girder the compression unit stress at failure was more than the yield point of the material.

The writer believes that it would be acceptable to design any of the girders listed in Table 11 by the gross moment of inertia method. The use of net moment of inertia seems to be an unnecessary refinement.

The plate girder is one of the most common types of structural members in use today, and its use as the principal member of large structures is increasing. The structural action of the plate girder is very complex and warrants much more study than has been given to it.

Considerable research has been conducted on many types of structural members, which has added to modern knowledge of their behavior. The column has proved a fruitful field of research since the Quebec Bridge disaster in 1907. Many column tests have been made in connection with the construction of some of the most important bridges. A very important series of tests of riveted tension members was conducted in connection with the building of the San Francisco-Oakland Bay Bridge. Whenever a structure is built which involves a quantity of eyebars, it is customary to specify full-size tests of several bars. The question is: Where can one find a report of tests of large plate girders made in connection with an important project?

The plate girder has not been subjected to any concerted program of research—possibly because no major disaster has occurred from the failure of such a member. The writer believes, however, that there is need for such tests and that as a result engineers would be able to design more intelligently and with greater economy.

CHARLES U. KRING,[37] JUN. AM. SOC. C. E. (by letter).—Apparently, the authors presuppose that the theoretically correct method of designing a plate girder is by use of the moment of inertia, and that the crucial question is: "What moment of inertia should be used?" No mention is made of the widely used "flange-area method," probably because they regard it as only an approximate makeshift. For finding the actual stress in the extreme fibers, that is undoubtedly true, but, for that purpose, so is the moment-of-inertia method only a makeshift, since, as the authors point out, the actual stress in some points of the flanges will have reached the yield point when the maximum stress as found by the moment-of-inertia method is only 18,000 lb per sq in.

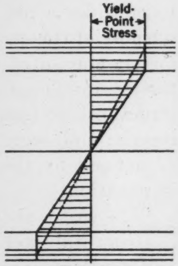

FIG. 11.

If it is agreed, then, that the ultimate aim of a method of design is not to produce a girder that will have a certain stress in the extreme fibers under the design load, but to produce a girder that will have a certain factor of safety under that load, then the writer believes it can be shown that, theoretically, the moment-of-inertia method is not as correct as the flange-area method.

A girder that is properly designed and properly braced against lateral buckling will fail by excessive deflection caused by plastic yielding of the flanges. The deflections will not be excessive, however, until the load is such that plastic yielding has occurred throughout the entire cross-sectional area of the flange.[38] Under that load, the ultimate load, the stress distribution will be as shown in Fig. 11. Under any less load, the stress in some fibers of the cross section of the flange will still be within the elastic range, and the deflections of the girder will still be of the magnitude of elastic deformations. Any additional load would cause the web to wrinkle and the girder to fail due to excessive deflection.

It is evident, then, that if a girder is designed by the flange-area method in which the allowable stress is assumed to be distributed uniformly over the entire flange area (net area in tension flange) the true factor of safety will be the yield-point stress of the material divided by the allowable stress. If 30,000 lb per sq in. were the yield-point stress and 18,000 lb per sq in. the allowable stress, the factor of safety would be 1.67. "Factor of safety" is defined herein as the ratio of the ultimate load to the design load. What the actual stress is at any point in the flange is not known, any more than it is when using the moment-of-inertia method, and, except where fatigue may be a factor, it is not important.

The flange-area method is slightly in error in regard to the addition of one-sixth the web area (one-eighth for tension flange) to the flange area, since under ultimate load it assumes the distribution of stress in the web to be as shown by the dotted line in Fig. 11. This error, however, is not only on the safe side (as an examination of Fig. 11 will show) but is also so small as to be negligible, except possibly in very shallow, heavy girders. Where the moment-of-inertia method is used, the factor of safety, even with the same allowable stress, will vary, being larger for shallow girders than for deep girders (as shown by the stress-distribution diagrams), and in no case will it be the yield-point stress divided by the allowable stress as is commonly assumed.

---

[37] Fellow, Civ. Eng., Univ. of Illinois, Urbana, Ill.

[38] "Theory of Limit Design," by J. A. Van den Broek, M. Am. Soc. C. E., *Proceedings*, February, 1939, p. 193.

From consideration of the foregoing, it is believed that the moment-of-inertia method is not only less theoretically sound than the flange-area method, but that the latter also satisfies the authors' requirement that "design methods should be as simple as possible."

THOMAS C. SHEDD,[39] M. AM. SOC. C. E. (by letter).—The first two sentences in the authors' introduction are: "It is customary for structural designers to consider a net moment of inertia in the design of plate girders. For the purpose of this paper, 'net moment of inertia' will be defined as the moment of inertia computed by deducting the effect of the material removed by holes in the tension flange." These sentences imply two things: First, that, in general, structural designers proportion plate girders on the basis of the moment of inertia; and, second, that in doing so they deal with the net moment of inertia as defined by the authors. There seems to be little basis in fact for either implication.

The writer always has been greatly interested in specifications for the design of structural steel bridges and buildings, and has studied minutely the changes and developments that have taken place since the first formal specification was issued by Clarke, Reeves and Company (later the Phoenix Bridge Company) on March 1, 1871. As a result the writer thinks it is the exception rather than the rule for structural designers to consider the moment of inertia of a girder, and even more exceptional for them to consider net moment of inertia as defined by the authors.

The fad for requiring the proportioning of plate girders by the "moment of inertia method" is a relatively recent and entirely unnecessary development. Quotations from some well-known specifications will give some clue as to when that development appeared.

The specifications issued by the American Railway Engineering Association in 1910 were widely used, and even more widely patterned after in the writing of other specifications. In that specification may be found:[40]

> "Plate girders shall be proportioned either by the moment of inertia of their net section; or by assuming that the flanges are concentrated at their centers of gravity; * * *."

These specifications represented general practice until they were superseded by the 1920 specifications, issued by the same organization. The 1920 specifications stated:[41]

---

[39] Prof., Structural Eng., Univ. of Illinois, Urbana, Ill.

[40] A.R.E.A. General Specifications for Steel Railway Bridges, Art. 29, 4th Ed., 1910.

[41] A.R.E.A. General Specifications for Steel Railway Bridges, Art. 116, 2nd Ed., May, 1923.

> "Plate girders shall be proportioned either by the moment of inertia of their net section including compression side; or by assuming that the flanges are concentrated at their centers of gravity."

A specification prepared and presented in 1923, by a committee of the Society, included the clause:[42]

> "Plate girders shall be proportioned by assuming that the flanges are concentrated at their centers of gravity, * * *."

A specification prepared by a joint committee of the Society and the American Railway Engineering Association, dated March, 1929, contained the statement:[43]

> "Plate girders shall be proportioned by the moment of inertia of their net sections, including the compression sides; or by assuming that the flanges are concentrated at their centers of gravity, * * *."

The original specification issued by the American Institute of Steel Construction contained the forerunner of present-day clauses in the form:[44]

> "Plate girders with webs fully spliced for tension and compression shall be so proportioned that the unit stress on the net section does not exceed the stresses specified in section five as determined by the moment of inertia of the net section."

It will be noted that this clause does not require that girders be proportioned by the so-called moment-of-inertia method—merely that they shall be so proportioned that fiber stresses computed from the net moment of inertia will not exceed a specified value. That requirement can be met easily and accurately without computing either the net or the gross moment of inertia.

The first widely accepted specification to adopt a definite requirement that girders be proportioned on the basis of the moment of inertia, as far as the writer knows, was the American Railway Engineering Association specification of 1935 which stated:[45]

> "Plate girders and other members subject to bending that produces net tension on one face shall be proportioned by the moment-of-inertia method, using the net section of the compression side as well as of the tension side."

This clause was revised in 1938 to read:[46]

> "Plate girders, I-beams, and other members subject to bending that produces tension on one face, shall be proportioned by the moment-of-inertia method. The neutral axis shall be taken along the center of gravity of the gross section. The tensile stress shall be computed from the moment of inertia of the entire net section and the compressive stress from the moment of inertia of the entire gross section."

[46] *Manual*, A.R.E.A. Specifications for Steel Railway Bridges, Art. 426, p. 15–15.

The writer can find little support, either in his experience or in an examination of specifications, for the authors' statements quoted at the beginning of this discussion. The definition of net moment of inertia given by the authors presumes a neutral axis resembling the edge of an old-fashioned bread knife. The most casual consideration of the flexed girder would seem to establish the plane of no stress as a continuous, smoothly curving surface which cannot depart more than an entirely negligible distance from the center of gravity of the gross section—it cannot conceivably "jitterbug" between the center of gravity of the gross section between holes and the center of gravity of the net section at holes.

To design plate girders by the moment-of-inertia method, as recommended by the authors, and required by many recent specifications, is an unnecessary waste of time and effort. It is an easy matter to proportion a girder by a simple modification of the commonly used "flange-area method," so that its extreme fiber stress, either on gross section or net section, will not exceed a specified value. One may proceed as follows:[47] Using the flange-area method, calculate the required net area of the tension flange in the ordinary way, multiply this area by the ratio of the estimated over-all depth to the estimated effective depth, proportion the girder, and check the estimated effective depth and the estimated over-all depth. If the estimated depths agree exactly with the actual values the girder as proportioned will have a calculated extreme fiber stress (using the moment-of-inertia method as defined in the specifications previously noted) not greater than the assumed value, and not less by more than 1% or 2% (usually less than 1%), except for very shallow and heavy girders, in which the discrepancy may be as much as 5%. If the differences between estimated depths and actual depths are considerable the designer will revise his calculations as he would in ordinary design. Obviously one may follow the same procedure if he prefers to design on the basis of gross area.

It should be clear that the flange-area method, when modified in the manner described,[47] would give exactly the same result as the moment-of-inertia method if effective depth were defined as the distance between the center of gravity of the compressive flange stresses and the center of gravity of the tensile flange stresses—the web area being translated into an equivalent flange area in substantially the usual manner.

In their conclusions the authors state that: "* * * the data from these tests point to the acceptability of the gross moment of inertia for design purposes." The writer is not sure he understands what is meant by the statement. If it means that one may compare girders he wishes to design with those which have been designed and built, with satisfactory results, on the basis of computations using gross moment of inertia, probably most engineers will agree, although they may not see any advantage in convenience or accuracy in so doing. If the statement is intended to convey the idea that one may apply the unit stress generally used on net section to gross section and secure a girder with the same margin of safety, the writer cannot agree—he finds no evidence in the data reported to support such a thesis.

---

[47] "Structural Design in Steel," by T. C. Shedd, John Wiley & Sons, Inc., 1934, p. 178 (first published in mimeograph form in 1928).

SCOTT B. LILLY,[48] M. AM. SOC. C. E., AND SAMUEL T. CARPENTER,[49] ASSOC. M. AM. SOC. C. E. (by letter).—The interest in this paper, as manifested by the many discussions, indicates that the structural design of plate girders is in a state of flux. The varied points of view that have been presented are of great value to all interested in this problem, and will be followed closely in planning future investigations.

As was to be expected, criticism of the writers' conclusions has been voiced by many discussers. On the other hand, all of the discussers who had experimental data to present have agreed that the gross moment of inertia is acceptable for design purposes. Although this agreement was indicated, several of the discussers based their conclusion on reasons which differ from those stated by the writers.

In general the discussions presented reflect the traditional thinking of the structural engineer in regard to net section as applied to tension members. The writers do not advocate the discarding of net-section rules for tension members, as so many discussers imply, but they wish to emphasize the fact that a plate girder is a structure in which tension and compression members are combined. They limited the original paper to the action of the girder under static loads within the working range, and were interested in over-all stress conditions rather than in the measurement of high localized stresses at, and around, the holes. The tests have shown that these strains are not greatly affected by these highly stressed areas, and that for all practical purposes the strains might be computed by the gross moment of inertia. Therefore, it is believed that the gross moment of inertia will represent working conditions of the girder more accurately than the net moment of inertia, since no matter what method of computation is used the real value of the high stress around the hole will be little affected. As several discussers have mentioned, these stress concentrations will be of importance if fatigue is a problem.

The tests also indicated that the over-all strains in the two flanges of the girder were practically the same, showing clearly that if the net-section advocates wish to be entirely right and consistent, they should deduct the holes from the compression flange as well as the tension flange. This is an elaborate statement of the fact that the stress concentrations exist in both flanges and that the rivets in the compression flange are no more effective in the so-called filling of the hole than those of the tension flange.

Although the writers restricted their paper to the action of a plate girder under static loads within the working range, the discussions indicate that the problem cannot be so limited. The discussions focus the attention on the compression flange rather than on the traditional tension flange. The writers often discussed failure by buckling while making the tests, but did not touch upon the subject in their paper. They regret this omission, but it has been ably discussed by several of the contributors, notably Mr. Hussey. Although the writers believe that their tests at working loads were sufficient to justify the use of the gross moment of inertia, a consideration of the stability of the compression flange makes more acceptable the use of the gross moment of inertia in design. This is true because in a failure by buckling a considerable portion of the girder is involved rather than a single cross section, and the gross moment of inertia tells more about the behavior of the entire structure.

---

[48] Prof., Civ. Eng., and Chairman, Div. of Eng., Swarthmore Coll., Swarthmore, Pa.

[49] Asst. Prof., Civ. Eng., Swarthmore Coll., Swarthmore, Pa.

The majority of the discussers seem to indicate that the use of the gross moment of inertia for determining deflections is common practice and such use is not questioned. The writers believe that this phase of the problem requires no more discussion, except to point out that in unusual cases Equation (5) is available to give a more accurate value of the effective moment of inertia.

The tests reported show that for all practical purposes the neutral axis may be considered at the centroid of the gross section, and that there is no indication of an undulating elastic line. It is true that a discontinuity exists in the stresses around the flange holes, and it is also apparent that conditions are the same in both flanges, giving a symmetrical cross section in this respect. By the principle of St. Venant, the boundary discontinuities will have no bearing on stresses normally expected in the interior of the web plate, and hence cannot affect the position of the neutral axis.

Neither the net moment of inertia, the gross moment of inertia, nor any other of the proposed methods of design gives the actual stresses in and around the holes of a plate girder. When the stress concentrations around such holes are given careful study, it becomes evident that no simple method can be used to evaluate them. They usually reach the yield point stress at the edge of the hole, and they cannot be modified by the methods of computation. The thought that a unit stress computed from a net moment of inertia gives a clearer idea of the safety of the plate girder is fallacious because plate girders do not fail by the rupture, or the tearing apart, of the tension flange.

If a high load is placed upon the girder, all parts of the tension flange will reach the yield point stress. Certainly then, if ever, the net section should govern because all stress concentrations have been wiped out. The compression and tension flanges will reach the yield point stress conditions at the same time. The tests made by the American Bridge Company, and reported by Mr. Hussey, show what happens when this condition is reached. The compression flange buckles and the plate girder fails—a functional failure—and the stresses and the stress concentrations in the tension flange are not vital factors. That is, these stresses did not measure the safety of the girder, so the traditional emphasis of the designer upon stresses computed in the tension flange by net-section methods has had no real bearing upon the safety of the girder. All of the tests reported by the discussers confirm these conclusions of the writers that safety does not lie in the computed stresses in the tension flange.

Mr. Osgood calls attention to an article by Friedrich Hartmann,[5] which should be read by every one interested in this subject.[5a] Professor Hartmann states:

> "The taking into account of the weakening effect due to rivets in those parts of a girder that are under tension was a matter of course so long as the static failure of these portions was considered as being the controlling factor in regard to safety. However, a girder becomes unfit for service much sooner, in general, when non-permissible deformations occur."

After a theoretical discussion calculated to give the basis for the foregoing statement, Mr. Hartmann describes the test of a pair of newly fabricated riveted girders made of open-hearth steel. These girders had a span of 10 m (32.81 ft), a depth-to-span ratio of approximately 0.1, and flanges of angles and cover plates. They were tested to destruction and failed by the buckling of the compression flange. The stress in the compression flange at failure slightly exceeded the compressive yield point of the material. Verification of this latter statement is noted in the tests reported by Mr. Hussey.

As stated, Mr. Hussey presented the data of a series of tests which bear directly on this problem. The plate girders were loaded to failure, and in every case except one the tension flange showed no distress and the compression flange failed by buckling. The one failure in the tension flange which Mr. Hussey reported occurred in a girder where the compression flange had twice the area of the tension flange. In general these tests supplied the data at failure requested by several of the discussers and bear out the statement of Mr. Hartmann that the safety of the girder is not controlled by the tension flange.

Professors Morris and Shank suggest methods of averaging the net sections with the gross sections to obtain flange stresses and a weighted moment of inertia, respectively. The writers believe that an average was obtained experimentally by using a 10-in. strain gage, since such measurements over the rivets (or holes) actually integrate the existing conditions.

Mr. Lane has expressed, very clearly, a thought that was uppermost in the minds of the writers, while they were planning the tests, when he stated: "*** riveted plate girder flanges will always consist of many small areas (adjacent to rivets) of high stress restrained and stiffened by surrounding areas of low stress." Highly stressed areas of this type have never given trouble.

Mr. Black computed the stresses in the riveted section of a rigid frame whose make-up was the same as that of a plate girder, and found that the measured stresses agreed with those obtained by using the gross moment of inertia. Mr. Moore reported tests made on an aluminum plate girder, in which he discovered that the stresses between rivets were higher than the stresses in the net section. He found that stresses computed from the gross moment of inertia correlated very well with those obtained by the use of a tensometer having a 0.5-in. gage length.

Mr. Jones has stated clearly the reasons for the adoption of the gross moment of inertia by the Committee on Specifications of the American Institute of Steel Construction. However, the writers want it clearly understood that the tests were not planned to confirm any action of any committee. They were designed to give essential data, and if the results seem to favor the gross moment of inertia it is simply because the confirmation is there.

The report of Professor Shedd on his careful research into the specifications of plate girders for the past fifty years is particularly valuable. Whether or not readers agree with Professor Shedd that girders should be proportioned by the "flange-area method," all will admit that as long as stresses govern the composition of flange areas, and the common theory of flexure is accepted, the moment of inertia, either gross or net, must be the final resort of the designer. The writers agree with Professor Shedd that the neutral axis does not resemble the old-fashioned bread knife.

The interest in the problems of the plate girder, which has been demonstrated by the large number of discussions, will insure many more investigations. The writers had only the results of two "pilot" test girders to guide them in writing their paper, but they are of the opinion that those tests, and the stimulating discussions, will go far in guiding future investigations, and hence will serve their major purpose. The writers are quite convinced that future investigations will be focused upon the compression flange rather than upon the tension flange. These future tests must include all types of cross sections of girders, varying degrees of restraint of the compression flange, and different depth-to-span ratios.

The writers close this discussion with the hope that each engineer will avail himself of any opportunity to test plate girders under working conditions and that he will also see to it that the results of his tests are given to the profession.

FIELD TESTS OF A SHALE FOUNDATION

By August E. Niederhoff,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Harry H. Hatch, Jacob Feld, Jack R. Rountree, and August E. Niederhoff.

Synopsis

Field tests described in this paper were conducted on the shale foundation of Possum Kingdom Dam on the Brazos River near Mineral Wells, Tex. They included time-settlement tests on various sizes of square plates, a cyclic loading test, and a series of tests to determine the effect of bond and coefficient of friction of concrete monoliths on a prepared shale foundation. The tabulated and graphical field data presented are analyzed in an attempt to verify some of the current theories advanced by students of soil mechanics. Comparison is also made between somewhat similar tests performed in the laboratory on smaller specimens. Formulas and permissible load values are suggested for this particular foundation material.

Introduction

The necessity of placing dams on difficult foundations is becoming increasingly frequent as the better sites are put to use and as more and more control and conservation of water is demanded by the public. The engineer is thus faced with the problem of using a "second best" or a "third" or "fourth best" site, as the case may be.

Possum Kingdom Dam, near Mineral Wells, is one of several on the Brazos River designed to control floods and conserve water for useful purposes. Design requirements as set up contemplated a masonry dam for a head of 130 ft, founded in the blue shale underlying the sand and gravel in the river-bed at a depth of approximately 20 ft. The procedure adopted was the usual one of examining available literature on shale foundations, performing specific tests and experiments on selected samples in the laboratory, seeking advice from experts and consultants and then making field tests under natural conditions. In due course certain information was acquired and, more important, certain preconceived notions as to the extent of available information and the con-

---

sistency of test results acquired with identical technique were proved to be in error. Many of these curious anomalies in the data cannot be explained. This paper is not intended to be a profound dissertation on soils mechanics or foundation theories; it is confined to a description and record of field tests and such observations and deductions as seem to be warranted by the results.

The literature on shale foundations gives an excellent "bird's-eye view" of the problem and serves as a reassurance that such foundations have been utilized successfully in the past. All too frequently, however, reports of tests are not sufficiently comprehensive enough, are vague in description, or lack conclusions that could have been substantiated by later measurements. For maximum benefit to the profession the important boundary conditions of a problem should be stated, with a description of the material, a full record of the tests, the final working loads used in the design of the structure and, if available, the deformation of the foundation under actual loads. This last requisite cannot be furnished by the writer but it is hoped that it may be partly supplied by others during discussion.

Purpose of Field Tests

The general purpose of the field tests was to obtain data on the probable movement of the masonry dam on the shale foundation when subjected to sustained loads and a repetition of loads. This general purpose was divided into five component parts, as follows: (1) To study the sliding of concrete placed on a prepared shale foundation, under the influence of horizontal and vertical loads; (2) to observe the fatigue effect on the shale when the load varied for several cycles from a maximum to a minimum unit load; (3) to determine the time effect on an area of the shale under the weight of a constant load; (4) to establish the relationship between various sizes of loaded areas under equal unit loads and the settlement of those areas; and (5) to compare values from large-scale models loaded under natural conditions with similar values obtained in the laboratory on selected specimens, under assumed and controlled conditions of drainage and temperature.

At the time the tests were proposed, it was realized that conclusive data on each of the foregoing items might not be obtained and that supplementary points of interest would occur to the investigators during the tests. Both of these things happened and the result was a progressive accumulation of knowledge. Fundamental assumptions made prior to the tests included the observation that failure would probably not occur from compressive stresses in the shale but from the tendency of the dam to slide on the contact plane between the masonry and the rock. This item was given primary consideration. Another fundamental assumption was that the shale was less rigid than the concrete dam above it and that the deformations would be confined to the shale.

Geology

The rocks at the dam site are sedimentary in character, consisting of a top member of limestone and grading downward through various admixtures of sandstone, silty and sandy shale, conglomerate and finally a fine-grained blue shale. The blue shale bed is approximately 80 ft deep and is supported from below by a hard gray sandstone of unknown depth. This general stratification is apparent on the cliff on the left bank and in the trenches that were dug in the sloping ground on the right bank of the river. The Brazos River has cut through these rock barriers successfully and is now about 300 ft below the top of the limestone cliff. The cemented conglomerate and the sand and gravel in the river-bed have probably been brought down from the headwaters during flood periods and deposited at the site.

The top part of the Wolf Mountain shale member immediately below the base of the overlying limestone and conglomerate has been oxidized and altered by waters that have seeped through the relatively porous limestone and conglomerate and have followed along the top of the impervious shale. The color has been changed by oxidation of the iron content from gray to yellow; calcareous cement has been dissolved and the shaley content softened to clay. Except for this weathered zone at the top of the formation and a moderate general penetration of surface weathering, the sandstone, sandy and silty shales, and blue shale phases of the formation are satisfactorily dense, strong, and impervious. The various phases of the Wolf Mountain formation appear to have adequate bearing strength.

The shale, including the silty phases, slakes in water after being dried. The slaking propensities vary considerably depending on its composition and texture. Therefore, it was necessary to observe the usual precautions against surface deterioration in all foundation excavations where concrete was placed.

The foregoing considerations indicate immediately the point of greatest danger; that is, the tendency of the shale to slake and form mud seams. One method of retarding this tendency during construction was to spray the exposed shale surface with an asphalt solution. This protective covering keeps the shale from drying and preserves its rock-like character. Since concrete must be placed on top of this protective coating, the degree of bond between the dam and foundation was unknown.

Laboratory Tests of Shale

Prior to making field tests, an extensive series of laboratory experiments were made with the shale at the Agricultural and Mechanical College at College Station, Tex. Additional tests were run at the Vicksburg Soils Laboratory conducted by the U. S. Army Engineers at Vicksburg, Miss. In general, the specimens were cut from cores taken by shot-drill methods during the exploratory boring and were carefully preserved until tested. The greater part of these tests were made on cylinders, 6 in. in diameter, 12 in. high, or on parts trimmed from the 6-in. cores. Although they varied over a wide range, the results of these tests were of a predictable nature and for the lower stresses indicated that the shale behaved as an elastic, isotropic material. The average results of the first tests conducted are as follows:

Test	Average results
(*a*) Moisture content, expressed as a percentage of the dry weight	7.85
(*b*) Percentage of total volume occupied by voids	15.4
(*c*) Absorption of water, expressed as a percentage of the total weight	0.25
(*d*) Modulus of elasticity, in pounds per square inch, at a compression of 7.2 tons per sq ft	133 000

Test	Average results
(*e*) Crushing strength of 6-in. by 12-in. cylinders, in tons per square foot	30
(*f*) Apparent specific gravity	2.46
(*g*) Weight per cubic foot undisturbed, in pounds	154
(*h*) Shearing parallel to bedding plane, in tons per square foot when compressed at 7.2 tons per sq ft	13.2
(*i*) Shearing normal to bedding plane, in tons per square foot when compressed at 3.6 tons per sq ft	8.35
(*j*) Chemical constituents, expressed as percentages of the total weight:	
Silica	62
Alumina	26
Lime	0.1
Magnesia	2.0
Potash and soda	some
(*k*) Cohesion, in tons per square foot (Vicksburg tests)	4.5
(*l*) Angle of internal friction, in degrees (Vicksburg tests)	45

Item (*c*) is not a standard or recognized test. The method used was to weigh specimens containing all of their natural moisture and then immerse them in water at room temperatures for periods varying from 3 to 20 days. It was noted that the specimens remained hard during this time and continued to absorb water for about 10 days. After the period of immersion the specimens were towel dried and re-weighed. The percentage of absorption was taken as the difference in the two weights, divided by the initial weight.

It is also to be noted that Items (*h*) and (*i*) fail to conform with tests (*k*) and (*l*) made at the Vicksburg laboratory. Disparity between results obtained by different laboratories, and even differences between several results obtained by the same laboratory, are the usual problems that confront a foundation engineer. A second series of tests covering essentially the same points gave slightly higher results and will be discussed subsequently under the comparison of laboratory and field experimental data.

In conducting the laboratory tests an attempt was made to duplicate the technique used in testing other earth, shale, and rock samples. New methods and refinement of apparatus were given some consideration but available time made it expedient to follow such rules as were known to have given good results in other cases. A further discussion of the laboratory tests is beyond the scope of this paper and they are mentioned merely to afford an over-all view of the material on which the field tests were conducted.

SLIDING OF CONCRETE BLOCKS ON A SHALE FOUNDATION

On the right bank of the Brazos River the concave side of Possum Kingdom Bend has a gently sloping surface that formed an ideal place to dig a test trench down to shale. At the point chosen for the trench the elevation of shale was higher than low water in the Brazos River and all experiments were conducted without interference from the river or from inadequate drainage. Conglomerate and sandstone were excavated with the aid of a small power shovel and dump trucks, after drilling and blasting. When blue shale was reached, it was excavated to within 12 in. of final grade and an asphalt sealing solution was applied to the surface to keep the moisture within the shale from escaping. Immediately prior to casting the concrete blocks in place the last 12 in. of shale were removed by air tools and by hand, the surface was cleaned by an air jet and another sealing coat of asphalt solution was applied. The foundation for the test blocks had a 5° slope upward in the same direction as the direction of the horizontal force that was to be applied. This sloping contact plane enters into computations for the resultant load and the angle of friction between concrete and rock. The tangent of the angle of the resultant load on this 5° sloping plane from a line normal to it is the ratio of parallel to normal forces. The parallel and normal forces are the vectoral summation of proper components of the vertical and horizontal loads. No special effort was made to secure a sandpaper finish on the shale foundation and the small irregularities from the use of the air tools were believed to be comparable to the surface that would be obtained under the dam when it was constructed.

The concrete test blocks were made from local aggregates, river water and Portland cement. Frequent checks indicated an average weight of 153 lb per cu ft and concrete test cylinders made at the time the blocks were cast, as well as cores later drilled from the test blocks, showed an average crushing strength of a 6-in. (diameter) by 12-in. (high) cylinder to be appreciably more than 3 000 lb per sq in. Eight test blocks, measuring 5 ft by 5 ft by 5 ft were cast in place, but only three of these gave significant information about the shale foundation.

The apparatus for the tests consisted of vertical and horizontal hydraulic jacks for applying loads, and dial gages for measuring movements of the block. Two hydraulic jacks resting on the top of the block, with an overhead, ballasted steel platform for backing, transmitted a controlled and registered vertical force (see Fig. 1). The overhead platform spanned the test trench and rested on rollers placed on ledges or berms cut in the sandstone on either side of the trench about 10 ft above the foundation (see Fig. 2).

The rollers made the platform movable along the trench axis so that when one test was completed the entire platform was wedged over until it was directly over the next test block. In this manner considerable time was saved in erecting apparatus for the eight tests. The ballast on the platform was sand confined in bags.

Horizontal loads (see Fig. 3) were applied by five hydraulic jacks working against the base of the concrete test block and using the side of the trench for backing. Fig. 4 shows the apparatus in place. Shoring and blocking were necessary to distribute the loads properly to the shale backing. Jacks and hydraulic gages were calibrated after the tests were finished. Entire units were placed in a 300 000-lb testing machine, the load applied, and the gages were calibrated accurately.

Horizontal movement of the concrete blocks was measured by four dial gages at the lower four corners of the block. Vertical movement was measured by two dial gages at the front and rear on the center line of the block near the top. These dial gages were sensitive to movements of 0.001 in. It required some

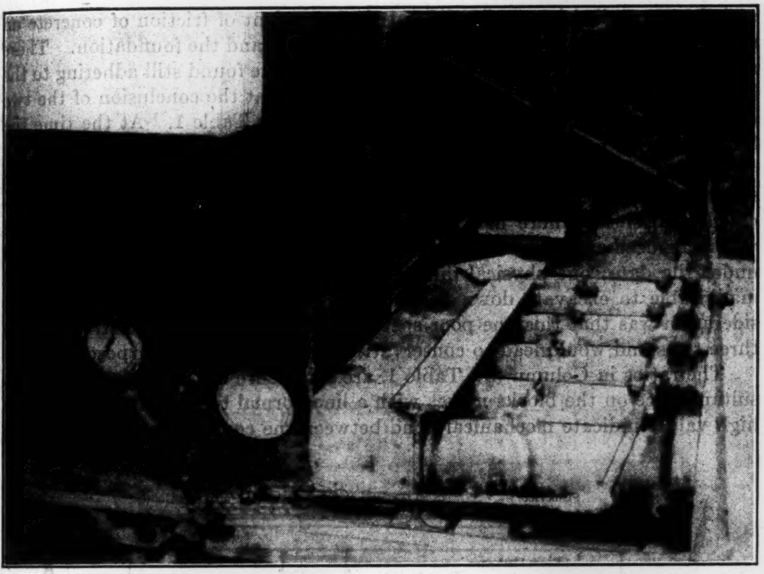

FIG. 3.—HYDRAULIC JACKS AND SHORING FOR HORIZONTAL LOAD APPLICATION

ingenuity to support these gages rigidly and independent from the test block. The framework finally used, as well as the relative positions of the six dial gages, is shown in Fig. 4.

The test procedure consisted of first applying the vertical load up to a predetermined value and then loading horizontally until the specimen failed. Movement of the block in a vertical and horizontal direction was recorded frequently during the loading. Time was kept from the beginning of the test until failure and a record was made at each reading interval to study the movement of the block.

* Percentage of the base area of the concrete test block to which shale was adhering after the test.

Data on the three blocks giving most information about the shale have been tabulated in Table 1. After failure of the specimens both loads were released and then reapplied in an effort to get the coefficient of friction of concrete on shale, uninfluenced by bond between the monolith and the foundation. These results, with a record of the percentage area of shale found still adhering to the bottom of the blocks when they were tipped over at the conclusion of the two tests described, are given in Columns (9) and (10), Table 1. At the time the blocks failed (when no greater resistance to a horizontal load could be obtained) small cracks appeared in the shale immediately beneath the block. These small cracks, apparent at the bottom corners of the blocks in the shale, indicated local shear failure near the surface. The foundation for Block No. 8 was recognized as soft and inferior to that which ordinarily would be permitted under the dam; but physical difficulties in equipment and drainage made it inadvisable to excavate down to good shale. The fact that was given consideration was that this one poor specimen reduced the average stress for the three tests and would lead to conservative values for design purposes.

The ratios in Column (8), Table 1, are a measure of the angle that the resultant force on the blocks makes with a line normal to the foundation. The high values indicate mechanical bond between the concrete and shale prior to

failure. The shear values in Column (5), Table 1, are taken along the plane of contact between the shale and concrete. They show an expected increase with the increase in normal load. The coefficients of friction of concrete on shale (Column (9), Table 1) include the effect of bottom irregularities in the foundation caused by scars and depressions from the use of hand tools in excavating. Subsequently these irregularities were filled with concrete when the block was cast in place. Visual inspection of the bottoms of the test blocks, when they were turned over upon completion of the tests, indicated that local shearing of the shale during the second test gave this rather high value for coefficient of friction. The time involved in the tests was a matter of minutes and corresponded to a "quick tests." This factor must be evaluated properly, particularly in any extrapolation of these data. A graphical stress-strain relationship is given in Fig. 5, the vertical load being kept constant for each of the tests, as follows:

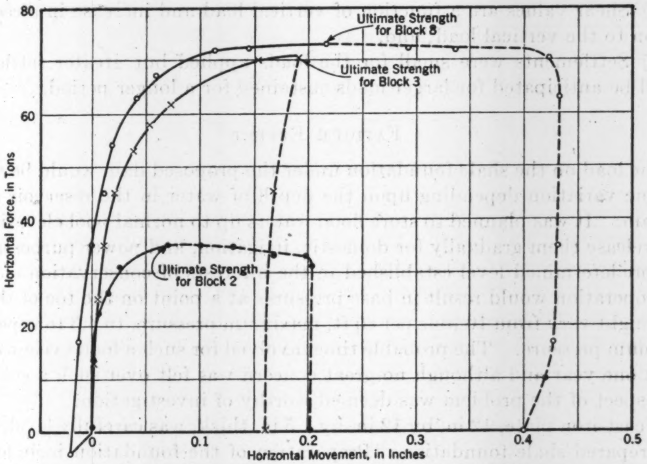

FIG. 5.—STRESS-STRAIN CURVES, BLOCKS 2, 3, AND 8

Test Block No.	Maximum vertical load, in tons
8	79.5
3	66.5
2	23.5

It should be noted in Fig. 5 that the specimens showed remarkable agreement with Hooke's law up to a fairly well defined point that might be termed the "yield point." This assumed yield point is about 63% of the ultimate strength and probably represents the first local failure in shear of a part of the shale immediately behind one of the protrusions of concrete that filled the irregularities of the surface of the foundation. The rate of increase in the ratio of horizontal load to vertical load was constant for all three specimens, to the point of ultimate strength.

The conclusions drawn from the foregoing data are:

(1) Bond existed between the concrete and shale in spite of the asphalt sealing solution that separated the two;

(2) The sealing solution preserved the rock-like qualities of the shale;

(3) If the dam is proportioned so that the ratio of the summation of horizontal forces to the summation of vertical forces does not exceed 0.50, a safe structure will result;

(4) Shear values are a function of vertical load and increase in direct proportion to the vertical load; and,

(5) Settlements were small for the loads applied but greater settlements should be anticipated for larger loads sustained for a longer period.

FATIGUE EFFECT

The load on the shale foundation under the proposed dam would be subject to some variation depending upon the depth of water in the reservoir behind the dam. It was planned to store flood waters up to normal pool elevation and then release them gradually for domestic, irrigation, and power purposes down to a predetermined level established in the interests of conservation of water. Such operation would result in base pressures at a point on the toe of the dam that might vary from 10 tons per sq ft, maximum pressure, to 4.3 tons per sq ft, minimum pressure. The probable time involved for such a load cycle would be about one year and although no great concern was felt over such a condition, this aspect of the problem was deemed worthy of investigation.

A cast-iron plate, 12 in. by 12 in. by 1.5 in. thick, was carefully leveled upon the prepared shale foundation. Preparation of the foundation included final hand excavation of shale and a sprayed application of an asphalt emulsion. This protective coating was renewed at 20-day intervals or as often as small patches showed wear from foot traffic. The cast-iron plate was seated upon a very thin layer of Portland cement mortar to obtain a level, horizontal surface and to fill the minute irregularities on the rock surface.

Controlled and registered vertical loads were applied through an hydraulic jack backed against a bin full of sand resting on an overhead platform. To assure axial application of the load a spherical bearing block was provided between the jack and the loading platform. Settlement readings were taken by means of small dial instruments measuring to 0.001 in. at the four corners of the test plate and at four points on the shale 6 in. removed from the edges of the plate.

A load cycle was considered complete when the pressure had been increased slowly to 10 tons and then decreased to 4.3 tons. In general, one cycle would require about six weeks during which time daily observations were taken of settlement, temperature, and weather. Some difficulty was experienced at first but corrections were soon made and the value of the test was not lost. Four cycles were completed in 246 days and the graphical record is indicated in Fig. 6.

In general, the shale behaved as an elastic material that would compress upon load application and rebound when the load was released during the first two cycles. The greatest average settlement of the four corners of the plate was 0.07 in., and 0.02 in. for the points on the shale 6 in. removed from the plate edge. The data are decidedly irregular and cannot logically be plotted as a stress-strain graph. In a gross manner it can be stated that there is a tendency toward elastic hysteresis since the "loading" line of a stress-strain graph does not coincide with the "unloading" line. This phenomenon was more apparent in laboratory tests of cyclic loading. A second observation is that the deformation at the end of the fourth cycle was more than that obtained in the first, second, and third cycles. There is a tendency for the settlement curve to flatten and become horizontal after repeated loadings, indicating some change in the structure of the rock. The permanent set of the area immediately under the test plate, and the slight upheaval of the points 6 in. removed from the plate, is typical of compaction and the probability of some plastic flow. However, the magnitudes of these movements of the foundation are small and it remains a matter of conjecture as to the number of loading cycles before definite fatigue effects could be noted. Certainly, for the loads involved in the test applied at the same rate for four cycles, the settlements are without structural significance. There is a recognized danger in assuming that a single test result on a specific, small area of rock can be used indiscriminately on the entire foundation. The difference between areas under test and under the prototype is too great to use the results of the experiment as any thing more than a trend or indication.

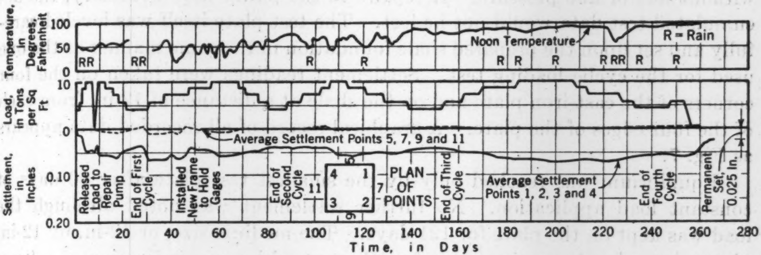

FIG. 6.—CYCLIC LOADING AND SETTLEMENTS, 12-INCH BY 12-INCH PLATE

TIME EFFECT ON SETTLEMENT

The time effect on settlement was investigated from the results of loading three cast-iron test plates and observing the settlement. Since the preparation and test procedure for obtaining the time effect is the same for all three plates, a description of only the 12-in. by 12-in. by 2-in. plate will be given. The final results will include data on all three plates. The dimensions of the other two plates were 6 in. by 6 in. by 2 in., and 24 in. by 24 in. by 2 in., respectively.

A registered and controlled vertical force was transmitted to the 12-in. by 12-in. plate through an hydraulic jack. The jack used the overhead loaded platform previously described, for backing, and axial application of the load was insured by a spherical bearing block between the jack and the platform. A refinement over the previous equipment consisted of a pressure regulator and check valve inserted in the pipe line between the pump and the jack. The pressure regulator gave constant pressure with a minimum of manual attention, and the check valve permitted withdrawal of the pump from the line without loss of line pressure. If repairs to the pump were necessary, the accumulated test data would not be lost. The test plate itself was leveled carefully and set upon the prepared shale foundation in the same manner as the one used for the cyclic loading test. Settlement readings were taken on the four corners of the cast-iron plate and on the shale at a distance of 12 in. from each of the four edges of the plate. A graphical record of all recorded data appears as Fig. 7.

Equilibrium was reached only by the smallest test plate after 60 days of constant load application. No further settlement was noted although the load was kept on the plate for 121 days. The medium size, or 12-in. by 12-in. plate, showed a decreasing rate of settlement with some indication of a "secondary" time effect after 70 days of constant load application. The large 24-in. by 24-in. plate continued to settle at a slow, uniform rate after the first 30 days of sustained load. The first 30 days was a period of decreasing rate of settlement.

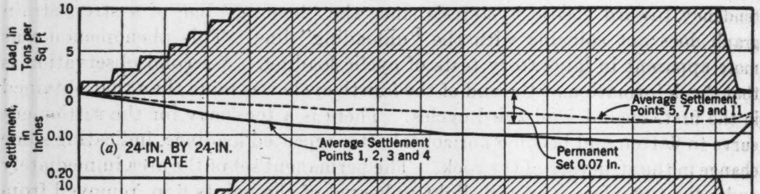

FIG. 7.—SETTLEMENT OBSERVATIONS UNDER LOADS OF TEN TONS PER SQUARE FOOT

Fig. 8 shows settlement plotted against time on a semi-logarithmic scale for the three plates. A smooth curve is drawn, based upon these points, and the difficulty of making simple, comprehensive statements from these test results is evident immediately. The three curves do not agree in shape. Although a general agreement of form can be said to exist for the time settlement curves for the medium and large plates, the data on the smallest plate do not give the same shape of curve. The conclusion drawn is that the rate of settlement is a function of the loaded area and the total load. Furthermore, the rate is slow enough (0.01 in. in 20 days for the largest plate) so that in the prototype the stability of the structure will not be affected. Continued settlement of the dam over a long period should be anticipated.

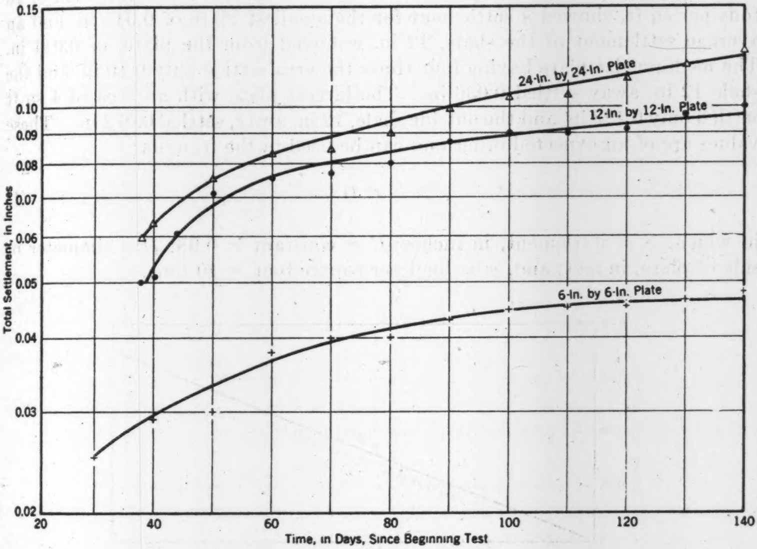

FIG. 8.—TIME-SETTLEMENT CURVES

The total settlement of the plates in all three cases was greater than the shale settlement 12 in. from the edge of the plates. No bulge in the surrounding shale was observed. This dish-shaped condition under load suggests that Boussinesq's formula, modified by a parameter, may be applicable. However, the Poisson's ratio of the shale is not known and a check on the foregoing supposition is precluded. No drift or plastic flow was discovered and settlement was a function of compaction only.

It has been stated[3] that the amount of settlement in soil is equal to the product of a constant depending upon the character of the soil, the diameter of the loaded area, and the unit load on the area. The tests on the three different sizes of square plates, each loaded with the same unit load, and founded on the same type of material, form the basis for establishing the relationship between the size of the loaded area and settlement. The equipment and tests are identical with that described under the heading "Time Effect on Settlement."

---

[3] "The Science of Foundations—Its Present and Future," by Charles Terzaghi, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 270.

The results of these tests, after 116 days under a constant unit load of 10 tons per sq ft, showed a settlement for the smallest plate of 0.048 in. and an average settlement of the shale, 12 in. removed from the plate, of 0.044 in. The medium size plate having four times the area settled only 0.10 in. and the shale 12 in. away settled 0.036 in. The largest plate with an area of 4 sq ft settled only 0.123 in. and the outside shale, 12 in. away, settled 0.072 in. These values are of an expected order and can be used in the formula

$$S = C\,D\,w \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which: S = settlement, in inches; C = constant = 0.08; D = diameter or side of plate, in feet; and, w = load per square foot = 10 tons.

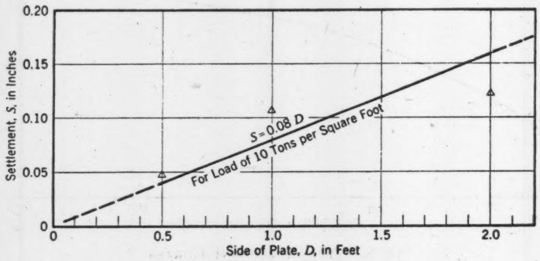

FIG. 9.—RELATION BETWEEN TEST RESULTS AND EQUATION (1)

Fig. 9 shows this relationship between experimental results and Equation (1) graphically; the straight-line variation may be assumed without too great a loss of accuracy. The deviations represent unexplainable phenomena that frequently crop up in foundation experiments in spite of painstaking efforts to insure comparable results.

Fig. 7 indicates that the permanent set under the 6-in. by 6-in. plate was 0.035 in. upon load release and 0.065 in. and 0.70 in., respectively, for the 12-in. by 12-in. plate and 24-in. by 24-in. plate when the load was released. This variation points to more compaction under the larger area and suggests that not only is the settlement under load a function of size but that the permanent set is likewise governed by the size of the loaded area.

The dish-shaped surface of the rock in the immediate vicinity of the three test plates indicates a cohesive medium offering resistance to shear. Since the shale around the smaller plate settled more than that around the 12-in. by 12-in. plate, it follows that there is some "edge effect" or disturbance. W. S. Housel,[8]

---

[8] "Notes on Soil Mechanics and Foundations," by Fred L. Plummer, M. Am. Soc. C. E., Edwards Brothers, Inc., Ann Arbor, Mich., 1936.

M. Am. Soc. C. E., has taken this factor into account in one of his older formulas for cohesive soils:

$$P = A\,m + l\,n \qquad (2)$$

in which: P = total allowable pressure in tons on footing; A = area of footing, in square feet; l = perimeter of footing in linear feet; and, m and n = two distinct constants. The constants can be established by considering the load causing equal settlement on two of the plates and checking against the third plate load for a similar settlement. This has been done for a settlement of 0.05 in. and the computed constants are $m = 6.2$ and $n = 0.525$. The agreement for other equal settlements is rather poor using these exact constants but there is no reasonable doubt that bearing capacity is a function of area and perimeter.

The conclusions that may be made from the experiments on loading and settlement of test plates on this shale foundation are:

(1) Cyclic loading of the foundation is not structurally important (the suspected plastic flow of the shale under repeated loads is small and at a slow rate);

(2) Continued settlement of the dam over a long interval at a slow rate can be expected logically;

(3) Careful proportioning of footings so that the larger footings carry smaller loads per square unit will prevent differential settlement; and,

(4) Edge effect of footings are important as well as the size of the loaded area.

CORRELATION OF LABORATORY AND FIELD TESTS

Rapid laboratory tests were made to determine shear and sliding values on small samples of shale 6 in. in diameter and about 2.5 in. high, on which was cast a neat sand-cement mortar cylinder of the same diameter and about the same height. The data in Table 2 can be compared with similar material for field tests on Blocks Nos. 2, 3, and 8, in Table 1. If the normal load is plotted against average shear (Item No. 2, Table 2), the resulting graph conforms to the equation

$$x = 3.7 + 0.9\,y \qquad (3)$$

TABLE 2.—LABORATORY OBSERVATIONS ON TEST BLOCKS

Item No.	Description	Normal Load, in Tons per Square Foot		
		10.8	7.2	3.6
1	Number of specimens	3	3	1
2	Average shear, in tons per square foot	12.46	10.8	6.9
3	Ratio of horizontal load to vertical load	1.15	1.50	1.91

One reason for the higher laboratory test values is that there was no asphalt coating separating the concrete and the shale. This is reflected by the lower bond or shear values for the field tests, amounting to an 81% reduction. Sliding friction was also lower by 28% for the field tests, for the same reason.

At the Vicksburg laboratory, three samples of shale were sandpapered smooth, coated with an asphalt sealing solution and a neat sand-cement mortar block was cast upon the top of the shale sample. The specimens were placed in a shearing apparatus with a known load normal to the plane of contact of the two materials, and then a load parallel to the contact plane was applied. After the slight bond was broken the coefficient of friction of the materials was 0.506. This value is 31% lower than that obtained by the field tests and gives a clear idea of the effect of irregularities in the contact plane in the field tests.

The shale was subjected to cyclic loading, at an accelerated rate, in the laboratory. A 6-in. by 12-in. cylinder of shale was placed in the center of a 16-gage corrugated iron culvert pipe 13.5 in. in diameter and 12 in. high. The annular space between the shale and the pipe was then filled with plaster of Paris. Load on the shale area 6 in. in diameter was applied through a disk measuring 4.91 in. in diameter. Compaction was measured by Ames gages. Two tests, for 16 and 24 cycles, respectively, varying from no load to 15.2 tons per sq ft gave a deformation of 0.006 in. and 0.0036 in. after four cycles. After sixteen cycles the permanent set was 0.0084 in. and 0.006 in. Elastic hysteresis and elastic after effects were both noted in these experiments. Likewise, it was apparent that the minimum deformation occurred under rapid application of load and an early release of that load. Since the conditions of the laboratory tests were totally different from the field tests no comparison is possible.

Several other unrelated facts were noted in the laboratory experiments, all of which defy comparison with the field tests. One of these was the 100% consolidation of a small shale specimen under a load of 3.576 tons per sq ft. Furthermore, by crushing many 6-in. cylinders of shale, 12 in. high, a general increase in crushing strength was noted for increase in depth at which the specimens were taken. This same relationship held for resistance to shear. Although this information "puts the final touches" to the pictured problem, greatest confidence is felt in the results of the field tests. Whatever else may be claimed about the field tests, it is undisputed that errors incident to sampling and to duplication of natural conditions are eliminated. It is believed that, in any comprehensive foundation investigation, the test results obtained in the laboratory should be supplemented by those taken in the field.

Loads Used in the Design of the Dam

Detailed plans were drawn for a gravity dam and a round-head buttress dam for the same site. The field tests indicated a safe bearing capacity of 10 tons per sq ft, assuming correct proportioning of footings. The maximum unit loads used in the design were 9.1 tons per sq ft for the gravity type of dam and 9.8 tons per sq ft for the round-head buttress type. The maximum average shear resistance on the plane of contact of these two types, with the foundation, was 2.3 and 3.6 tons per sq ft, respectively. This compares favorably with the field tests of 5.1 tons per sq ft under a much smaller vertical force. The ratio of the horizontal to the vertical forces used in design was 0.332 for the gravity dam and 0.486 for the round-head buttress dam. This is about six-tenths of the ultimate values from the field tests, 0.812.

DISCUSSION

Harry H. Hatch,[4] M. Am. Soc. C. E. (by letter).—Considering the individuality of every foundation material or its constituent soil particles, the difference in location and climatic conditions, the manner of, and personal equation in, investigation, and the variation in the experience, competence, and viewpoints of the investigators, one cannot be surprised that "consistency of test results," reported in this paper, is lacking.

The apparently negative result of a conscientious test is just as important as if its results agreed one hundred per cent with the preconceived notions. It is desirable to standardize tests and testing methods for the sake of economy of time and money; but on no job should an engineer be content with the "patent medicine" laboratory theories and notions. He should explore further, by independent research, to find the truth for the case in hand.

Only recently have the rule-of-thumb methods been discarded and scientific investigation applied to these jobs. Sufficient data are not available yet even to suggest a law of averages. It is essential that all such investigations should yield concise information in regard to the purpose and the method of conducting any test that is not well known or standardized. It is all the more important, therefore, to have before the profession the accurate description and results of every investigation of this nature in order to augment the store of information and knowledge on the subject; and the author should be commended for his purpose and efforts in presenting this paper.

Under the heading "Laboratory Tests of Shale," Items (*h*) and (*i*) do not entirely fail to conform with Items (*k*) and (*l*).

$$s = \frac{W}{A} \tan \phi + C \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which: s = unit shear; $\frac{W}{A}$ = normal unit load = external load per foot of area; ϕ = angle of internal friction; and C = unit cohesion.

The computed shear value for Item (*h*), according to Equation (4), is $7.2 \tan 45° + 4.5 = 11.7$ tons per sq ft, or 88.9% of the observed value, 13.2; and similarly for Item (*i*), it is $3.6 \tan 45° + 4.5 = 8.1$ tons per sq ft, or 97% of the actual value, 8.35. Items (*k*) and (*l*), therefore, give values about 11% and 3% less than the actual; and unless this consistency is purely by coincidence, the test results cannot be considered seriously in error.

The writer's experience has been that the coefficient of friction (and hence the angle of internal friction) is not constant for a given soil, and that it decreases with the increase of pressure. If C, the cohesion, is kept constant at 4.5 in order to have the actual and the computed shear values agree completely, the angle of internal friction should be 50° 23′ and 46° 55′ for Items (*h*) and (*i*), respectively, in this case. That is, the higher the pressure the larger the angle of internal friction will be, which does not agree with the writer's contention. Could the solid rock formation and its bedding planes account for this? On the contrary, with due respect to the difference in their normal loads, the actual shearing value parallel to bedding plane is higher than that normal to bedding plane, instead of vice versa as would be expected. Perhaps, after all, bedding planes in this solid rock may not be of any consequence during the shearing tests; or the value given to cohesion may be responsible for the inconsistency. More details as to the number of tests conducted for the two planes, with their individual results under different pressures and with a description of the method of averaging them, will be necessary to interpret the given averages intelligently.

---

[4] Div. Engr., Springfield Water Works, Springfield, Mass.

There are only two average shear values given. More would have been desirable, but these two will satisfy Equation (4) with the assumed constants $\phi = 53° 25'$ and $C = 3.5$ (see Fig. 10(*a*)). A description of the author's methods of testing cohesion and the angle of internal friction of a solid rock formation will be of interest and may throw some light on the subject.

Equations (4) and (3) are identical. In the latter $x = s$, the shearing force in tons per square foot; and $y = \frac{W}{A}$, the normal pressure in tons per square foot. Therefore, $C = 3.7$, and $\tan \phi = 0.9$, or $\phi = 42°$. As already stated, ϕ cannot remain constant as the pressure increases, even if shearing value increases with the increase of pressure. However, this relation does not follow the locus of a straight line, as given by Equations (3) and (4). Either equation is only approximate and, when obtained from the plottings of only two or three points, the equation becomes entirely inapplicable. In Fig. 10(*b*), Curve *A* gives the relation between Columns (2) and (5) of Table 1; Curve *B* is the plot of Item No. 2, Table 2; and *C* is the plot of Equation (3). According to Equation (3), or Curve *C* in Fig. 10(*b*), there are 3.7 tons per sq ft of cohesion between the concrete and the shale. Can there be any such cohesion between the concrete and the shale blocks? With no cohesion existing between the blocks, the extension of Curves *A* and *B* down to the origin can well be justified. From Fig. 10(*b*), it is perfectly evident that the relation between shear and normal pressure can be represented neither by a straight line, nor by a simple exponential equation, over the entire range.

From a practical point of view, what necessity is there for cohesion tests and angle of internal friction tests when actual shearing tests are likely to give a much better picture of the existing conditions in the structure?

It is preferable to have as many direct shear tests as possible under the circumstances, but a sufficient number of them at any rate, and to plot them all in order to obtain a more or less representative graph showing the relation between the shear and normal load, without paying any attention to the uncertain term of the angle of internal friction of a solid rock formation or its cohesion.

As stated by the author, the asphalt coating separating the concrete and the shale must have acted as a lubricating plane between the two and was mostly responsible for the lower shear and coefficient of friction values. Due to the asphalt alone, disregarding any other possible reason, it is questionable whether the two sets of test results can be considered comparable.

Although the two sets of tests may be unlike in more ways than one, the behavior of the coefficient of friction in both cases is according to the writer's experience; namely, the coefficient of friction is not constant, but decreases with the increase of vertical pressure. Insufficient data are available, however, to produce for this job a representative graph or equation expressing the relation between the coefficient of friction and the vertical load. Any such relation obtained from two or three tests would be practically of no value.

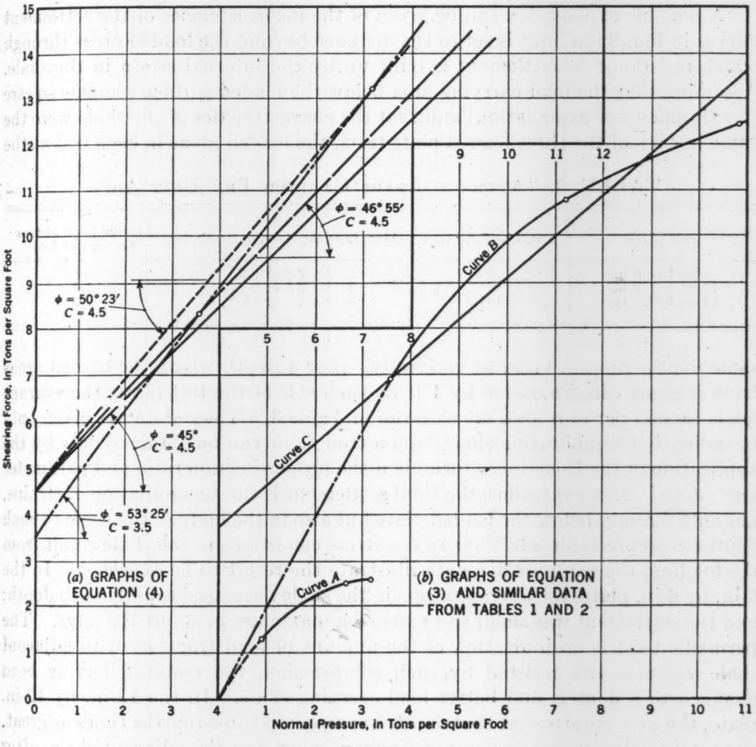

FIG. 10

JACOB FELD,[5] M. AM. SOC. C. E. (by letter).—A complete and unbiased description of field and laboratory tests, carefully planned and executed, is given in this paper. The value of the large-scale field tests is without question; the author's admitted lack of success in making the laboratory test results agree with the field test results should be considered a marked contribution to the study of foundations. No more valuable warning can be cited of the dangers from indiscriminate extrapolation of small-scale laboratory tests for use in design, unless such tests are tempered by actual experience with similar foundation materials or superseded by large-scale field tests.

---

[5] Cons. Engr., New York, N. Y.

As Mr. Niederhoff explains, the shale seemed to follow the laws of elasticity up to certain unit loadings, but with definite plastic flow characteristics.

A possible explanation can be given of the inconsistencies of the settlement curves in Fig. 8 if a limit is set to the distance beyond the loaded areas through which resistance to settlement is built up by the internal strain in the shale. Assuming that the load-carrying area below the loaded surface remains square (for simplicity of explanation) and that the characteristics of the shale were the same in each of the three loaded plate tests, the loaded areas in each test at the same depths are not stressed uniformly. For a depth where the loaded areas have increased in dimension by 1 ft on each side of the test plate, the average loads carried per unit area are as given in Table 3. These data are given only to indicate the qualitative effect; and a true value can be obtained only by the application of the Boussinesq formula if the proper Poisson ratio and parameter are known. However, since the total settlement is the accumulation of strains, not only directly below the loaded plate but also in the body of the shale to such depths as appreciable additions to the stress conditions in the shale result from the loading, the comparative data illustrate the result to be expected. In the 6-in. by 6-in. plate, the average stress in the shale decreased rapidly with depth; and the settlement was small and reached a maximum in about 100 days. The permanent set is an indication of the amount of load transferred to adjacent shale volumes and resisted by such compression, the material having been changed to a denser, and better load-carrying shale. In the 12-in. by 12-in. plate, the average stress at that depth was two and three fourths times as great, the total settlement was correspondingly greater, and the adjacent shale, after 140 days, had not yet taken up the load by being compressed. In the 24-in. by 24-in. plate, the same condition was also true to a larger degree.

TABLE 3.—AVERAGE LOADS CARRIED PER UNIT AREA

Test plate	Total load, in tons	Area, in square feet, at depth d	Avenue load, in tons per square foot
6 in. by 6 in.	2.5	2.5 by 2.5 or 6.25	0.4
12 in. by 12 in.	10	3 by 3 or 9	1.1
24 in. by 24 in.	40	4 by 4 or 16	2.5

An attempt to apply the results of a 6-in. by 6-in. test plate to the design of a dam foundation under the same unit loading can result only in unforeseen and apparently unexplainable settlements.

The description and results of the large-scale shear tests in shales are especially valuable as an addition to the compilation of data on foundation phenomena.

JACK R. ROUNTREE,[6] **JUN. AM. SOC. C. E.** (by letter).—The author is to be commended not only for presenting an interesting and valuable paper, but also for his purpose in placing before the profession a complete record of a carefully planned series of field tests. The results of only a few such tests have been published in engineering literature. In general, the physical properties of different shales are quite different; therefore it is seldom that the results of any one test may be correctly applied to a case at hand. A compilation of test results covering many types of shales, nevertheless, may be of considerable value in estimating the limits between which might fall the properties of a particular shale foundation.

---

[6] Asst. Structural Engr., TVA, Knoxville, Tenn.

This paper sets forth a very practicable field test for determining the resistance to sliding. The fissile character of some shales precludes the possibility of obtaining representative specimens large enough to be tested in the laboratory; in such instances, the engineer must necessarily resort to field tests in order to investigate the resistance to sliding. It is significant that the author recommends field tests to supplement laboratory tests, in "any comprehensive foundation investigation."

In many cases of dam construction, the contact surface between the foundation and the concrete is very irregular, and the problem of evaluating the resistance to sliding is reduced to a determination of the shearing strength of the foundation material. The sliding tests described by Mr. Niederhoff are well suited to the investigation of shearing strength of a shale foundation. At Test Block No. 8, where the underlying shale was described as "soft and inferior to that which ordinarily would be permitted under the dam," the failure evidently occurred within the shale, rather than at the contact surface; in this instance, the test results give a measure of the ultimate shearing strength of the "inferior" shale. In all cases where failure may occur within the shale it is believed advisable to remove lateral support by excavating a shallow trench around the boundary of the shear area. For a large shear area, such as that beneath a monolith of a gravity type dam, lateral support around the boundary of the area may have only a negligible effect upon the total shearing resistance. For small areas, however, this effect may be significant.

A series of tests conducted at the site of Watts Bar Dam on the Tennessee River in Tennessee represents an example in which the test methods and apparatus described by the author have been adopted in the testing of a different type of shale foundation. Due to distinct differences between the Watts Bar and Possum Kingdom shales, the results of the two series of tests are not similar. The Watts Bar tests were conducted by the Tennessee Valley Authority, in conjunction with the U. S. Army Engineers, for the purpose of determining the shearing strength of the shale in a direction parallel to the bedding planes.

The shale underlying the easterly portion of Watts Bar Dam is a part of the Rome formation and is classified as a cemented, clay and silty shale. It is fairly compact and, in general, unweathered. The shale is characterized as "fissile" and is comprised of very thin layers which are easily separated; the surfaces of these layers are smooth and glossy in appearance. The shale is interbedded with thin layers of hard sandstone which vary from ⅛ in. to 2 in. in thickness and which are normally from 1 in. to 24 in. apart. In general, the shale has a dip angle of from 20° to 30°, but occasionally, in limited areas, the bedding planes are horizontal. The apparent weakness of the material against movement parallel to the bedding prompted these tests.

Six concrete test blocks, 5 ft long, 3 ft wide, and about 4.5 ft high, were cast directly on the shale foundation. The contact surfaces were parallel to the bedding planes and were as nearly horizontal as the nature of the rock permitted. In contrast to the Possum Kingdom tests, where it was assumed that failure would occur by sliding of the concrete on the shale, the Watts Bar tests were predicated upon the assumption that failure would occur within the shale at a short distance below the contact surface. Immediately prior to testing, the shale around each block was trenched out to a depth of about 2 in. below the projection of the contact surface. Trenches were located about 6 in. from the edges of the blocks, and were carefully prepared by hand tools to insure that no shale under the contact surfaces was disturbed. At each block this trench served to remove lateral support from around a short prism of shale, thereby simulating the conditions existing for a large contact area, for which lateral support around the boundary of the area would afford very little, if any, additional shear resistance.

TABLE 4.—TEST DATA, WATTS BAR DAM, TENNESSEE

No.	Description	Test Blocks Nos.:					
		1	2	3	4	5	6
1	Preliminary period of sustained vertical load, in minutes	65	70	55	74	None	None
2	Increments of horizontal load, in pounds	5 000	5 000	5 000	5 000	5 000	10 000
3	Average rate of application of horizontal load, in pounds per minute	9 700	7 300	1 600	1 700	6 500	6 600
	Intensity of Load, in Tons per Square Foot, Parallel to Contact Surface:						
4	At failure	3.08	5.06	1.84	3.03	1.83	2.20
5	Estimated failure under sustained load	2.46	4.13	1.51	2.46	1.50	1.81
6	First sliding	2.30	3.31	1.51	2.53	1.34	2.20
7	Second sliding	1.46	2.06	2.86	1.32	....	....
	Intensity of Load, in Tons per Square Foot, Normal to Contact Surface:						
8	At failure	5.71	4.36	2.07	5.10	2.03	4.88
9	Estimated failure under sustained load	5.65	4.26	2.05	5.06	2.02	4.86
10	First sliding	5.63	4.18	2.05	5.06	2.00	4.88
11	Second sliding	3.10	2.11	5.10	2.52	....	....

The methods of loading the blocks and of measuring the deformations were similar to those described by Mr. Niederhoff. The general procedure consisted of bringing the vertical load up to a specified intensity, and then loading the block with increments of horizontal load until failure occurred. Deformations were observed after each increment of horizontal load had been applied. The failure point was taken to be that point at which a constant horizontal load produced a continued movement of the test block. After failure, all loads were relieved; the vertical load was then brought up to a specified intensity, and the horizontal load applied gradually until a slow, uniform sliding of the block was produced.

The speed of testing used at each block varied somewhat, as shown by Items Nos. 1, 2, and 3 of Table 4. After testing, each block was tipped over to allow inspection of the failure surface. At all blocks, the failure surfaces were from ¼ in. to 2 in. below, and essentially parallel to the contact surfaces; the shale was well bonded to the under side of the concrete test blocks. Similar failure surfaces were observed under Blocks Nos. 1, 3, 4, and 5; at Block No. 2, the failure occurred along a decidedly irregular surface; at Block No. 6, the failure surface was more nearly plane than at any other block, due to the exceptionally smooth bedding at that location.

At Blocks Nos. 1, 2, 3, and 4, the vertical load was sustained for a short period before application of the horizontal load. The effects of vertical deformation during the short period of sustained vertical load probably increased somewhat the shear strength of the material; under a long-time loading, such as during the construction period of a large gravity-type structure, a similar but more pronounced increase might logically be expected.

Fig. 11 shows the average horizontal deformation plotted against horizontal jack load, for Test Block No. 4. Similar curves were observed at all blocks except at Block No. 6. Fig. 12 shows the variation in the instantaneous value of the rate of change of deformation with respect to the horizontal jack load for Test Block No. 4; this curve suggests that progressive permanent yielding (shearing off of projections on the failure surface) occurred only in the vicinity of the failure load. Construction of curves similar to Fig. 12 for other test blocks led to the adoption of a value of 83% of the ultimate horizontal load as the average point of "break" in the deformation curves; a sustained horizontal load of this amount might finally produce failure; therefore this reduced amount is a more conservative measure of the strength of the material than the

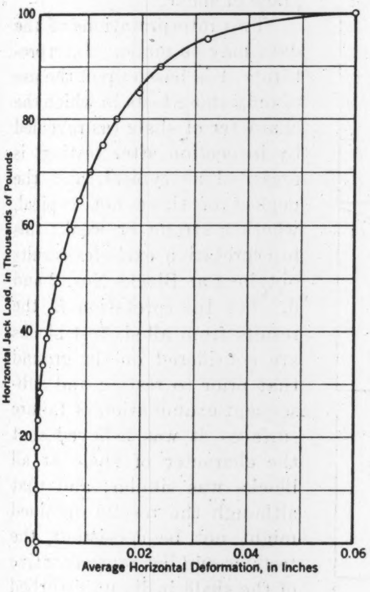

FIG. 11.—AVERAGE HORIZONTAL DEFORMATION, TEST BLOCK NO. 4

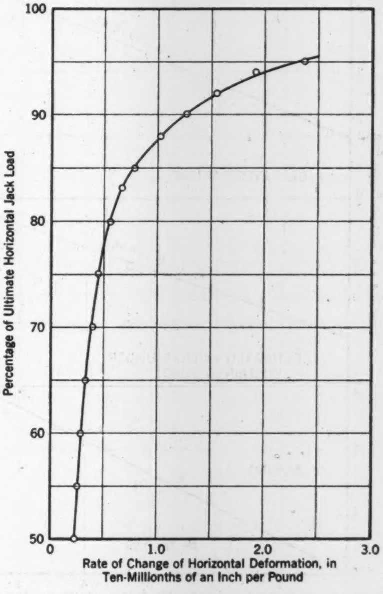

FIG. 12.—RATE OF CHANGE OF HORIZONTAL DEFORMATION WITH RESPECT TO HORIZONTAL JACK LOAD, TEST BLOCK NO. 4

ultimate failure strength indicated by the tests. Items Nos. 4 to 11 of Table 4 show the essential data obtained from the tests; the "estimated failure under sustained load" (Items Nos. 5 and 9) is based upon a horizontal load equal to 83% of the observed failure load.

In the interpretation of the test data, the internal friction theory as originated by Coulomb is used on the ground that it has been accepted by many engineers and that it affords a means of interpreting the data in a systematic manner. The resistance to movement is given by the expression:

$$s = s_1 + k\,q \quad \text{..........................(5)}$$

in which s is the total unit shearing strength, s_1 is the shearing strength under conditions of no load (pure shear strength), k is the factor of shearing-strength increase (assumed to be constant), and q is the intensity of load on the plane of shear.

Two interpretations of the data may be made. Interpretation *A* is based upon the use of only those tests in which the character of shale (as revealed by inspection after testing) is regarded as typical, and the neglect of those not typical, whether strong or weak; this interpretation excludes results obtained at Blocks Nos. 2 and 6. For Interpretation *B*, the results from all six test blocks are considered on the ground that prior to testing and subsequent examination of failure surfaces, it was believed that the character of shale at all blocks was similar, and that although the results obtained might not be consistent, the tests would be representative of the shale in its undisturbed form.

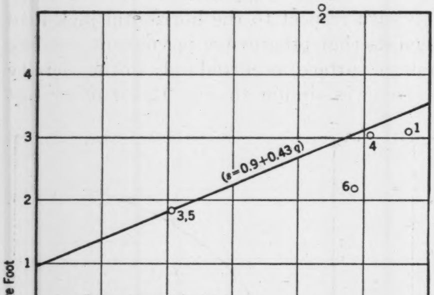

FIG. 13

The shearing strength of the shale is appraised at a value intermediate between those of the respective interpretations. Using the data for the observed failure loads, Equation (5) may be written (in units of tons per square foot):

$$s = 0.9 + 0.43\,q \quad \text{..........................(6)}$$

Fig. 13(*a*) shows the position of the straight line defined by Equation (6), together with the plotted points. The expression for the shearing strength based upon the "estimated failure under sustained load" data is:

$$s = 0.8 + 0.35\,q \qquad (7)$$

Fig. 13(*b*) shows the position of this straight line together with the plotted points from which Equation (7) was determined.

The sliding tests made after failure of the test blocks are the basis of the points plotted in Fig. 13(*c*). For the first four test blocks, sliding tests were made for two different intensities of vertical load. Assuming that s_1 in Equation (5) equals zero, a mean value of the coefficient of friction may be obtained for each block by constructing a straight line through the origin and through the average of the points obtained from the sliding tests for that block. Excluding the results at Block No. 2, an average value of the coefficient of friction of shale sliding on shale, parallel to the bedding planes, is 0.53, as shown by the slope of the straight line of Fig. 13(*c*).

The coefficient of friction so determined is probably too high; extension of the straight lines of Figs. 13(*c*) and 13(*a*) will indicate that, under higher normal loads, the resistance to sliding is greater than the total shearing strength. During the process of sliding, shearing off of projections on the failure surface continued; thus the construction of the straight line of Fig. 13(*c*) through the origin is probably not valid in this case.

The successful application of the Possum Kingdom test methods to the conditions existing for the Watts Bar tests affords additional proof of the value of Mr. Niederhoff's paper.

AUGUST E. NIEDERHOFF,[7] ASSOC. M. AM. SOC. C. E. (by letter).—One cannot but envy the delightfully simple routine of yesteryear's foundation engineer. His only field test for suitable rock was to hit it with a hammer and if the hammer rang, the rock was considered acceptable. Since that time loads have become heavier and more complex as superstructures have become larger. Engineers began to worry a little bit and took small samples of rock from the foundation to the laboratory where they could experiment on the "hand-picked" specimens. As long as the rock was hard and durable these laboratory tests were reassuring. No qualms of fear were felt that this quick analysis, wherein the specimen failed all at once like the poetic "one-hoss shay," did not give dependable results. Today, not only are the loads heavy but the foundation material is usually poor. There is also a dawning realization that there must be something to this fourth dimension concept sometimes called "time-effect" or "fatigue of materials." Also there is the growing suspicion that all foundations are not perfectly elastic media able to withstand the ravages of exposure; so the engineer again turns to field tests. The conduct of these field tests and the interpretation placed upon the results by the writer have elicited the views of several engineers. At least two cases in widely separated parts of the United States are known in which the field testing procedure, as described in this paper, has subsequently been used in whole or in part, yielding excellent results. The record is completed by the interesting and readable discussions of this paper that have added much to the store of knowledge on foundations.

---

[7] Civ. Engr., U. S. Army Engrs., U. S. Engr. Office, Portland, Ore.

Mr. Hatch contributes the observation that agreement between several laboratory results is reasonably good if they are properly evaluated. Using shear values derived from Equation (4) he finds the variation of consistency to be about 11 per cent. This is certainly within acceptable limits, but in the same paragraph he points out that laboratory shear values parallel to the bedding plane exceed those normal to the bedding plane. The expectation is naturally for results in the opposite direction and forms the basis for the writer's contention that laboratory tests should be taken with "a grain of salt." Too often they include numerous errors of sampling and duplication of natural conditions.

It is claimed that by experience Mr. Hatch has found that the coefficient of friction decreases with an increase in pressure. In Fig. 10 he has plotted shearing force against normal pressure, and the curved lines for both laboratory and field tests prove his point. The curves, of course, do not pass through the origin because there was evidence of definite adhesion between the concrete blocks and the shale. Another point that could be emphasized in Fig. 10 is the similarity of shape in the curves of the field and laboratory results. This unsuspected conformity between the two types of data is reassuring.

From a practical point of view it is debatable whether determining the angle of internal friction for a system composed of different materials such as concrete and shale, or for shale alone, is less important than knowing the actual shear value of the material. The writer believes both are important but that the answer in any particular case is necessarily influenced by the local conditions of contact between the concrete and the shale. For instance, a deep, narrow cut-off trench dug into the shale and filled with concrete to form a shear key presents one problem, whereas the same foundation using a pattern of small grooves cut into the shale to increase resistance to sliding is something quite different. Apparently the relative importance of shear values *versus* internal friction values must be decided on the merits of a particular case. In any event, determining the ratio of horizontal to vertical loads furnishes designers with a recognizable value. It is the kind of thing that gives them a comfortable feeling if they are sure their assumption is on the safe side.

For the foundation under consideration in the paper, the field data, and to a lesser extent the laboratory results, were enough to serve for the conclusions at the end of the section headed "Sliding of Concrete Blocks on a Shale Foundation." Criticism as to basing opinions upon a few tests can only be answered by the statement that even three field tests are preferable to having no results whatever. Limitations of money, time, and opportunity still harass the foundation engineer as well as other research professions.

The writer is pleased to note that Mr. Feld is of the same opinion regarding the dangers of extrapolating small laboratory tests to fit an entire foundation. The only time that this is excusable is when the failure values of small unconfined specimens are many times the actual loads to be placed on the foundation. Even then an engineer should run through preliminary calculations that tend to show that such a case actually exists. Table 3 demonstrates this procedure very nicely in addition to being an explanation of inconsistencies in the settlement curves in Fig. 8. Since writing the paper the author has noted that the presence of overburden loads in the proximity of the largest test plate may also have been responsible for erratic settlement. All of the test plates were placed in the bottom of a trench but the distance from the edge of the largest plate to the toe of the cut was a smaller proportion of plate diameter than was the case of the other two test plates. If the tests were to be done again the writer would see that no other loads were closer to the edges of the tested area than four diameters of the test plate. Mr. Feld is quite correct in his statement that tests and interpretations must be tempered by experience.

It is regrettable that discussion did not bring out actual measurements of settlement on Possum Kingdom Dam during construction. Data of this nature, if made available in the future, would be most conclusive as to the efficacy of the field and laboratory tests.

Mr. Rountree's discussion is clearly illustrated with results of tests conducted along similar lines and is one of the two aforementioned cases in which it is known that the test procedure has been used successfully. His observation that test blocks should not include the lateral support of abutting shale because of probability of erroneous interpretation of results is sound advice.

The fissile character of the foundation of Watts Bar Dam appears to make it a more difficult problem than that faced by the writer. The Tennessee Valley Authority has been known to adopt the best engineering methods in solving difficult design and construction problems and their decision to use field tests in this case illustrates the alertness of their engineering personnel. The writer was fortunate in having the opportunity of discussing these experiments with their engineers at Knoxville, Tenn., prior to the actual running of the tests. Agreement was reached that by no other means could a more lucid picture be given of the results of biaxial loading of a laminated shale foundation. The use of six test blocks and the several observations of various phases during and after the experiments guaranteed the maximum amount of information from these tests.

Equation (5) is the generalization of Equation (3) of the paper; and, as pointed out in one of the other discussions, the relation between shear and normal pressure is not a straight line over the entire range. In Fig. 13(*a*), it is possible to draw a smooth curve through all points except 6, indicating a somewhat smaller value of shearing strength under conditions of no load than that obtained by Mr. Rountree's analysis. This smooth but irregular curve does not pass through the origin, confirming the fact that shear occurred in the shale and not principally along the contact plane of the concrete and shale.

Acknowledgments.—Tests described in the paper were made as a part of the investigation and design of Possum Kingdom Dam by the U. S. Army Engineers. After the completion of investigation and detailed plans the dam was built under the direction of a State agency employing a firm of private engineers. For the Army Engineers, Captain H. A. Montgomery was District Engineer in charge. Acting Principal Engineer, W. L. Kuehnle, Assoc. M. Am. Soc. C. E., exercised supervision over the conduct of the tests and offered valuable suggestions and observations. The part of the paper under "Geology" was prepared from the report of Warren J. Mead,[8] Affiliate Am. Soc. C. E., submitted to the district engineer.

The writer is pleased to acknowledge the excellent assistance of Logan Woolley, Jun. Am. Soc. C. E., and Mr. Edwin Jensen in the compilation and recording of data. The preparation of this paper and the interpretation of test results were among the duties of the writer. Messrs. Jensen and Floyd Johnson, formerly of the U. S. Army Engineer Office at Mineral Wells, Tex., directed the field work.

RELATION OF THE STATISTICAL THEORY OF TURBULENCE TO HYDRAULICS

BY A. A. KALINSKE,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. HUNTER ROUSE, MARTIN A. MASON, J. C. STEVENS, BORIS A. BAKHMETEFF, CLYDE W. HUBBARD, JOHN S. MCNOWN, SAMUEL SHULITS, PAUL NEMENYI, BENNIE N. NETZER, AND A. A. KALINSKE.

SYNOPSIS

The basic principles of the statistical theory of fluid turbulence are outlined in this paper. Only those ideas and conceptions of importance in hydraulics problems are presented; the more complicated mathematical details are omitted. Turbulence can be characterized by intensity parameters which are the root mean square values of the fluctuating velocity components, and a length parameter proportional to the most probable eddy size. The specific parameters used in characterizing the energy dissipation and the diffusion power of turbulence are derived, and experimental techniques and data are presented to illustrate how these parameters are obtained. The two major problems in hydraulics in which knowledge of the turbulence mechanism is of importance are those involving the increase or decrease of energy dissipation, and the transportation of sedimentary materials. The practical application of the theories of turbulence to some specific problems is indicated. The experimental data were obtained by injecting color streams and suspended immiscible liquid droplets into turbulent water streams and by using motion-picture photography.

PURPOSE OF PAPER

Since about 1930, both in Europe and in the United States, considerable research on fluid flow has been concerned with the fundamental aspects of the mechanism of fluid turbulence. In aeronautics, wind-tunnel and atmospheric turbulence has been an important field of research since about 1925. Some of the findings of the aeronautics engineers and physicists have been permeating gradually into the hydraulics literature. Certain fundamental investigations

on water turbulence have been conducted, and more and more are being started. However, all this talk and writing about turbulence generally leaves the practical hydraulic engineer quite uninterested. The practical usefulness, either immediate or future, of knowledge relating to turbulence does not seem very apparent.

It is the purpose of this paper to correlate the knowledge of fluid turbulence with the solution of some practical hydraulics problems, and to present the information on fluid turbulence, already in existence, in a more simplified form. Some experimental data obtained by the writer and others will be presented, and various experimental techniques for obtaining pertinent information on liquid turbulence will be discussed.

What Is Turbulence?

Turbulence, as it is present in wind-tunnel air streams, has been studied for some time and has gradually attracted the attention of hydraulics engineers, because there are many hydraulics problems which would be better understood if more were known of the mechanism of turbulence.

When observing turbulence by injecting a dye or some other material into water, or when observing smoke coming from a chimney, a most haphazard mixing process is seen, seemingly unpredictable in nature. Fundamentally, it may be said that a fluid at any point is in a state of turbulence if the direction and magnitude of its velocity vector vary irregularly with time. This variation is relatively rapid and in general cannot be predicted except in the probability sense. Turbulence may be caused as a result of high shearing stresses set up in a fluid in motion, by obstructions in the path of a fluid, by passing a fluid through a screen or honeycomb, or by some means such as mechanical stirring. Confusion has arisen in the minds of some regarding whether or not there is a definite periodic relationship between a velocity component at a single point with respect to time. True turbulence is of an entirely random nature without any kind of regular periodicity. A stream of discrete vortices which form directly behind a body immersed in a moving fluid, such as the von Kármán vortex street, is not true turbulence; it is referred to as vortex motion, which breaks down eventually into true turbulence.

Turbulence manifests itself in the form of large and small eddies, whirling about from one layer of fluid to another. These eddies can transfer momentum, mass, heat, etc., from layer to layer, and can also cause the high dissipation of energy that characterizes turbulent flow. It is apparent then that, to characterize various quantities regarding turbulence (such as, for instance, the size of the eddies, the velocity at a point, or the frequency of velocity fluctuation), average quantities must be dealt with and the principles of statistics employed in determining and in using these quantities. Additional fundamental ideas regarding turbulence can be found in the writings of H. L. Dryden,[2] Hunter Rouse,[3] Assoc. M. Am. Soc. C. E., and Boris A. Bakhmeteff,[4] M. Am. Soc. C. E.

BASIC PRINCIPLES OF STATISTICAL THEORY OF TURBULENCE

At the outset let it be noted that a complete and mathematically rigorous theory of turbulence has not as yet been developed. However, as far as the hydraulics engineer is concerned, such a theory, even if available, would be of little use. The mathematical difficulties are so great that the development of a rigorous analysis has taxed some of the best mathematical minds. The various ideas that have helped greatly in understanding the mechanism of turbulence are those developed by L. Prandtl,[5] G. I. Taylor,[6] and Theodor von Kármán,[7] M. Am. Soc. C. E. The basic statistical principles they have set forth have been checked experimentally, and are of fundamental importance in an understanding of the turbulence mechanism.

It is convenient to represent the varying velocity vector at any point in turbulent flow by means of the velocity components along three rectangular axes. The velocity in the direction of mean flow, which is taken along the x-axis, at any instant is represented as $(U \pm u)$, in which U is the mean velocity in that direction and u is the fluctuation in that direction. Obviously, the arithmetic mean of u is zero. The velocity along the other two axes, y and z, is represented as $(V \pm v)$ and $(W \pm w)$, respectively. If the mean flow is in the x-direction, V and W are zero. Since u, v, and w are quantities that vary with time, it is useful to represent them by certain statistical averages. Before this is done, the statistical distribution of these quantities should be investigated. That is, what is the form, for instance, of $f(v)$ which is a function such that $f(v_i)\, dv$ indicates the probability that the value of v lies between v_i and $v_i + dv$? Such a function, $f(v)$, is called a statistical distribution function. If the value of v could be determined at any point for a sufficiently long period of time the general form of $f(v)$ could be found.

The value of the velocity component v with respect to time is shown in Fig. 1. These data were obtained in a turbulent water stream at a point near the center of a 12-in. by 12-in. open channel where the mean velocity was 7.8 in. per sec (see heading "Experimental Technique"). A block diagram indicating the frequency of occurrence of various values of v is shown in Fig. 2. The smooth curve in Fig. 2 has the equation,

$$f(v) = y = \frac{1}{\sqrt{2\,\pi}\,\sqrt{\overline{v^2}}}\, e^{-a v^2} \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which: $a = \dfrac{1}{2\,\overline{v^2}}$, to simplify typography, and $\sqrt{\overline{v^2}} = 0.725$ for the data in Fig. 1. The bar over a term or terms indicates a mean taken with respect to time.

This is the ordinary normal error law. Other investigators[8] have found the same type of distribution law, thus indicating the random nature of the velocity fluctuations. If the distribution function is of the same general form, different degrees of turbulence can be indicated by some average value of the quantities u, v, and w. The most significant average is that called the root mean square, or standard deviation, designated as $\sqrt{\overline{v^2}}$, for instance. The standard deviation indicates the spread of the distribution curve; also, its square, such as $\overline{v^2}$, is proportional to the energy of the turbulence for that velocity component.

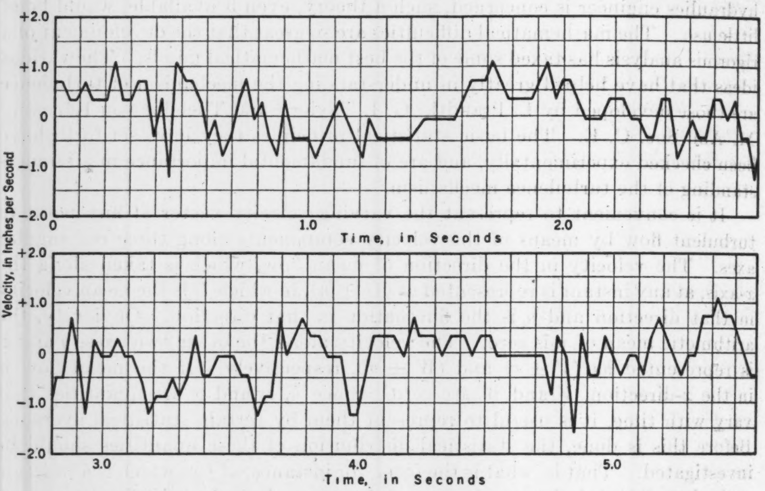

FIG. 1.—TRANSVERSE VELOCITY FLUCTUATION FOR TURBULENT FLOW IN A CHANNEL

Various types of turbulence can be designated depending on the relative magnitude and interrelationship of u, v, and w. The simplest type of turbulence, from the mathematical viewpoint, is that referred to as isotropic turbulence. In this type of turbulence $\overline{v^2} = \overline{u^2} = \overline{w^2}$, and also quantities of the type $\overline{u\,v}$, $\overline{u\,w}$, and $\overline{v\,w}$ are zero. These terms are referred to as mean products in statistics. If quantities such as $\overline{u\,v}$ are different from zero, a mean shearing stress and a mean velocity gradient exist in the fluid. In ordinary two-dimensional flow the mean shear stress, τ, is represented as,

$$\tau = \rho\, \overline{v\,u} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which ρ = unit density. A simple derivation of this is given by Messrs. Rouse[3] and Bakhmeteff.[4] Isotropic turbulence, therefore, cannot exist near a boundary. It is only approached in the center of large conduits and in artificially created turbulence, such as that beyond screens or grids. The turbulence beyond a hydraulic jump probably approaches isotropy.

Another fundamental concept that is useful in discussing turbulence is that of the correlation coefficient. In order to characterize a turbulent condition more completely, in addition to the quantities $\overline{u^2}$, $\overline{v^2}$, and $\overline{w^2}$, which characterize the intensity of the turbulence, a scale factor is necessary. Two different turbulent flows may have the same intensity, but the average size of the eddies may be entirely different. In order to identify the scale of the turbulence, Professor Taylor[6] has suggested that the instantaneous velocity components, either v or u, be measured simultaneously at two different points, along either the x-axis or the y-axis, over an appreciable period of time. Suppose v is measured simultaneously at two points a distance x apart. Let v_1 be the velocity at one point and v_2 that at the other point at the same instant, and define a number R_x such that,

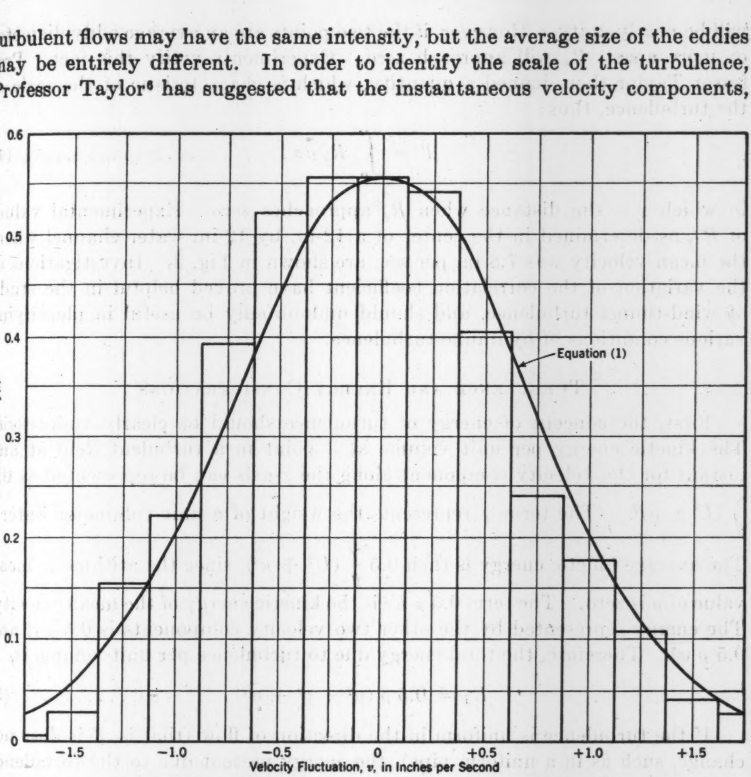

FIG. 2.—FREQUENCY DISTRIBUTION CURVE FOR TRANSVERSE VELOCITY FLUCTUATION

$$R_x = 1 - \frac{\overline{(v_1 - v_2)^2}}{2\,\overline{v^2}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3a)$$

Since $\overline{v_1^2} = \overline{v_2^2} = \overline{v^2}$ Equation (3a) can be transformed into

$$R_x = \frac{\overline{v_1\,v_2}}{\overline{v^2}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3b)$$

The term R_x is known in statistics as a correlation coefficient. Now, if the two points are close so that they are within the average size eddy, v_1 and v_2 will tend to be of approximately equal magnitude and of the same sign, and R_x

will be nearly unity. However, if the two points are an average eddy diameter or more apart, R_x will approach zero. Experiments verify this fact. Professor Taylor then defined a quantity, which is characteristic of the scale of the turbulence, thus:

$$l' = \int_0^x R_x \, dx \ldots\ldots\ldots\ldots (4)$$

in which x = the distance when R_x approaches zero. Experimental values of R_x, as determined in the center of a 12-in. by 12-in. water channel where the mean velocity was 7.8 in. per sec, are shown in Fig. 3. Investigations of the variation of the correlation coefficient have proved helpful in the study of wind-tunnel turbulence, and should undoubtedly be useful in identifying various conditions of hydraulic turbulence.

TURBULENCE AND ENERGY CONSIDERATIONS

First, the concept of energy of turbulence should be clearly understood. The kinetic energy per unit volume at a point in a turbulent fluid at any instant for the velocity component along the x-axis can be represented as $0.5 \frac{\gamma}{g} (U \pm u)^2$. (The term γ represents the weight of a unit volume of water.) The average kinetic energy is then $0.5 \frac{\gamma}{g} (U^2 + \overline{u^2})$, since the arithmetic mean value of u is zero. The term $0.5 \rho U^2$ is the kinetic energy of the mean velocity. The energy represented by the other two velocity components is $0.5 \rho \overline{v^2}$ and $0.5 \rho \overline{w^2}$. Therefore, the total energy due to turbulence per unit volume is,

$$E_T = 0.5 \rho (\overline{u^2} + \overline{v^2} + \overline{w^2}) \ldots\ldots\ldots\ldots (5)$$

If the turbulence is uniform in the direction of flow (that is, if it does not change, such as in a uniform pipe), the energy present due to the turbulence need not be taken into account in any energy equation. However, if the energy of turbulence varies from point to point, such as occurs in conduit expansions, beyond bends, through valves, etc., its omission, in any study of energy changes, results in an error. An important item regarding turbulent energy is that it is a form of degraded energy and will eventually be transformed into heat, and can never be recovered.

How does turbulence cause the dissipation of energy? All energy is dissipated into heat through the action of viscosity. If there were no viscosity, there would be practically no energy loss, and any turbulent energy created, such as in a sudden expansion, would tend to persist indefinitely. The high internal shear stresses set up by the turbulent eddies cause the large energy dissipation in turbulent flow.

In pipe flow, for instance, potential energy is being dissipated constantly into the form of heat. For turbulent flow, a simplified derivation for the rate of transference of the potential energy producing flow into energy of turbulence is as follows: Let the mean tangential shearing stress at a point in a circular pipe be τ. The mean difference in velocity between two layers of fluid is ΔU.

The work done per unit time by the force τ on an area $(\Delta x \, \Delta z)$ is then equal to $(\tau \, \Delta U \, \Delta x \, \Delta z)$. The work done per unit of time per unit volume of fluid is $\tau \frac{\Delta U}{\Delta y}$, or, in the limit, $\tau \frac{dU}{dy}$, in which $\frac{dU}{dy}$ is the mean velocity gradient. The mean unit shearing stress, τ, at a point distant y from the center of a pipe, of radius r is equal to:

$$\tau = \frac{h_f \, y \, \gamma}{2 \, L} \quad \text{.......................} (6)$$

in which: h_f = loss of pressure head in pipe length, L, and γ = unit fluid weight. This shear stress can also be represented as,

$$\tau = \mu \frac{dU}{dy} + \rho \, \epsilon \frac{dU}{dy} \quad \text{.......................} (7)$$

in which: μ = viscosity; ρ = unit density; and ϵ = mechanical viscosity due to turbulence (may vary from point to point). Except near the wall, in fully developed turbulent flow, the quantity $\mu \frac{dU}{dy}$ is very small in comparison to $\rho \, \epsilon \frac{dU}{dy}$. Thus in turbulent flow most of the potential energy is first transferred into turbulent energy at a rate represented by $\tau \frac{dU}{dy}$ per unit volume. The turbulent energy is then changed into heat by the action of viscosity. The rate at which potential energy is transferred into turbulent energy is not necessarily equal to the rate of energy dissipation into heat, at any one point. The turbulent energy can be diffused to other points by the action of the eddies, and then dissipated into heat.

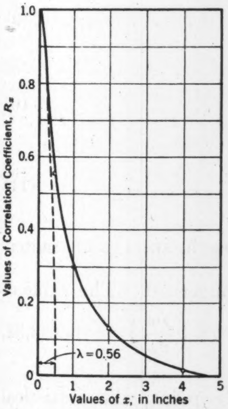

FIG. 3.—DISTANCE CORRELATION COEFFICIENT FOR TRANSVERSE VELOCITY, v

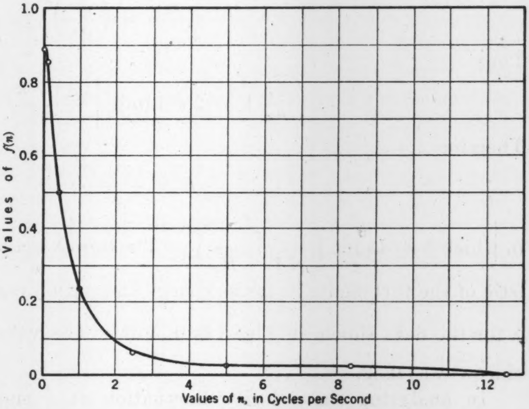

FIG. 4.—DISTRIBUTION OF TURBULENT ENERGY AMONG DIFFERENT FREQUENCIES

The mechanism by which turbulent energy is dissipated into heat is quite complicated, even in the simple case of isotropic turbulence. The rate of this energy dissipation is proportional to the viscosity times the mean square of the various instantaneous turbulent velocity gradients—that is, quantities such as $\mu \overline{\left(\frac{\partial v}{\partial x}\right)^2}$. The partial derivative sign is used because the component v also varies with y and z. The general formula for turbulent energy dissipation is given and discussed by Professor Taylor.[9] For isotropic turbulence Professor Taylor has shown that the mean rate of dissipation of energy per unit volume of fluid is:

$$K = 7.5\, \mu \overline{\left(\frac{\partial v}{\partial x}\right)^2} \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

Various simple relations exist between the different mean turbulent velocity gradients in isotropic turbulence. For instance $\overline{\left(\frac{\partial v}{\partial x}\right)^2} = \overline{\left(\frac{\partial u}{\partial y}\right)^2}$, and $\overline{\left(\frac{\partial v}{\partial y}\right)^2} = \overline{\left(\frac{\partial u}{\partial x}\right)^2}$.

One method of determining the value of a quantity such as $\overline{\left(\frac{\partial v}{\partial x}\right)^2}$ is by use of the correlation coefficient concept. Recalling the definition of R_x from Equations (3), if the values $\overline{(v_1 - v_2)^2}$ are obtained for small values of x, then approximately,

$$\frac{\overline{(v_1 - v_2)^2}}{x^2} = \overline{\left(\frac{\partial v}{\partial x}\right)^2} \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

Thus,

$$\overline{\left(\frac{\partial v}{\partial x}\right)^2} = 2\, \overline{v^2} \operatorname*{Limit}_{x \to 0} \left[\frac{(1 - R_x)}{x^2}\right] \ldots\ldots\ldots\ldots (10)$$

Therefore,

$$K = \frac{15\, \mu\, \overline{v^2}}{\lambda^2} \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

in which $\lambda = \operatorname*{Limit}_{x \to 0} \left(\frac{x}{\sqrt{1 - R_x}}\right)$. The term λ is a length, and is a characteristic of the turbulence as far as energy dissipation is concerned. The value of λ for the data shown in Fig. 3 is 0.56 in. The value of $\overline{\left(\frac{\partial v}{\partial x}\right)^2}$ is then 3.32, since $\overline{v^2}$ was 0.52.

In analyzing the velocity fluctuation at a single point, the statistical distribution function was found to indicate the frequency of occurrence of various values of v, as shown in Figs. 1 and 2. It is of interest to make a similar type of statistical analysis of the distribution of the energy of the turbulence, such as $0.5\, \rho\, \overline{v^2}$, among the various frequencies. This will be useful in showing what is the average magnitude of the frequency of the velocity fluctuation. A function $f(n)$ is to be determined such that $f(n)\,dn$ indicates the most probable proportion of the total energy, as represented by $0.5\,\rho\,\overline{v^2}$, lying between the frequencies n and $(n + dn)$. More exactly, $f(n)\,dn$ does not indicate the fractional part of the total energy lying between the frequencies n and $(n + dn)$, but rather, the probability of the total energy lying in that range of frequencies. The method of the determination of $f(n)$, from experimental velocity fluctuation data, has been indicated by the writer in a previous paper.[10] It can be shown that,

---

[9] "Statistical Theory of Turbulence," by G. I. Taylor, *Proceedings*, Royal Soc. of London, Vol. 151A, 1935, p. 430.

$$\overline{\left(\frac{\partial v}{\partial x}\right)^2} = \frac{4\,\pi^2\,\overline{v^2}\,\overline{n^2}}{U^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

in which $\overline{n^2} = \int_0^\infty n^2 f(n)\,dn$, since $\int_0^\infty f(n)\,dn = 1$. A plotting of $f(n)$ against n is shown in Fig. 4 for the velocity data shown partly in Fig. 1. The value of $\sqrt{\overline{n^2}} = 3.25$ and that of $\overline{\left(\frac{\partial v}{\partial x}\right)^2}$ is 3.56. This determination of $\overline{\left(\frac{\partial v}{\partial x}\right)^2}$ checks very well with the calculation by the correlation coefficient method as given by Equation (10). That the two methods are mathematically equivalent can be demonstrated. However, different data are used in each method to obtain the same final result.

DIFFUSION CHARACTERISTICS OF TURBULENCE

Turbulence eddies are capable of causing the exchange of momentum, heat, matter, etc., from one layer of fluid to another. Near solid boundaries the existence of a mean velocity gradient across a turbulent fluid indicates that momentum is being transferred from one layer of fluid to another. A temperature gradient indicates the transfer of heat; and a suspended material gradient in a turbulent stream indicates the transfer of matter. The characterization of a turbulent flow as to its diffusing or exchange power is an important item in any investigation of turbulence. The process of mixing in a turbulent fluid stream is often referred to as "eddy diffusion."

The laws of molecular diffusion have been applied to mass transfer processes in turbulent fluid streams.[11] However, the complete validity of this procedure is open to question, since the motion of fluid masses is not comparable to that of gas molecules. A common and convenient method of studying the diffusing power of turbulence is to observe the spread of heat, matter, or color from a point source of the heat, matter, or color injected in the turbulent fluid stream. Experiments were made by injecting a constant stream of color through a fine tube, and also by injecting colored droplets of a mixture of carbon tetrachloride and benzol, having the same specific gravity as water, and photographing the transverse spread of the color, or the droplets, with a motion-picture camera. The important quantity to determine from such experiments is the mean square cross-stream or transverse travel of the color at various distances downstream from the point of injection. Fig. 5 shows some sketches of typical motion-picture frames of the color and the droplets. The transverse travel at any distance x downstream is called Y and its mean square value $\overline{Y^2}$. Professor Taylor[12] has developed a theory relating x and $\overline{Y^2}$. His general premise is that the statistical correlation between the velocity of a fluid mass at one instant and at another later instant is high when the time interval is small, and this correlation approaches zero when the interval becomes large. This theory shows that $\overline{Y^2}$ varies as x^2 for small values of x, and gradually approaches a direct variation with x, as x increases. Professor Taylor[12] showed that

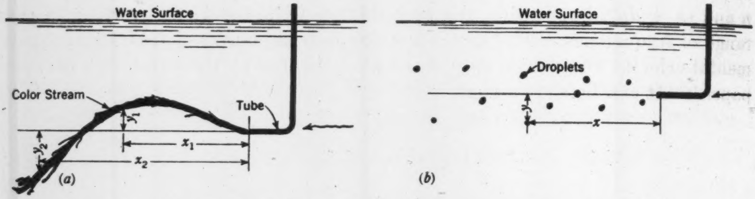

FIG. 5.—SKETCHES OF TYPICAL MOTION-PICTURE FRAMES, SHOWING COLOR STREAM, (a), AND COLORED IMMISCIBLE DROPLETS, (b)

$$0.5\,\frac{d\overline{Y^2}}{dt} = \overline{v^2}\int_0^t R_t\,dt \qquad (13)$$

in which: $\overline{v^2}$ = mean square transverse velocity fluctuation; R_t = correlation coefficient between velocity of a fluid mass at one instant and at an instant, t, later $= \frac{\overline{v\,v_t}}{\overline{v^2}}$; $t = \frac{x}{U}$; and U = the mean forward velocity. When R_t is near unity $\int_0^t R_t\,dt$ is equal to t and $\overline{Y^2}$ is given by:

$$\overline{Y^2} = \frac{\overline{v^2}\,x^2}{U^2} \qquad (14)$$

When R_t approaches zero, $\int_0^t R_t\,dt$ becomes a constant, k, and $\overline{Y^2}$ is given by:

$$\overline{Y^2} = \frac{2\,\overline{v^2}\,k\,x}{U} \qquad (15)$$

Fig. 6 shows experimental data obtained by the writer on the relation of $\overline{Y^2}$ and x in a turbulent water stream near the center of a 12-in. by 12-in. open channel at a point where the mean velocity was 7.8 in. per sec and $\sqrt{\overline{v^2}}$ was 0.78 in. per sec. Note the initial linear relationship of $\sqrt{\overline{Y^2}}$ and x; and at larger values of x, the linear relationship of $\overline{Y^2}$ and x. Note also that the initial slope of the $\sqrt{\overline{Y^2}}$-curve determines the value of $\sqrt{\overline{v^2}}$ according to Equation (14).

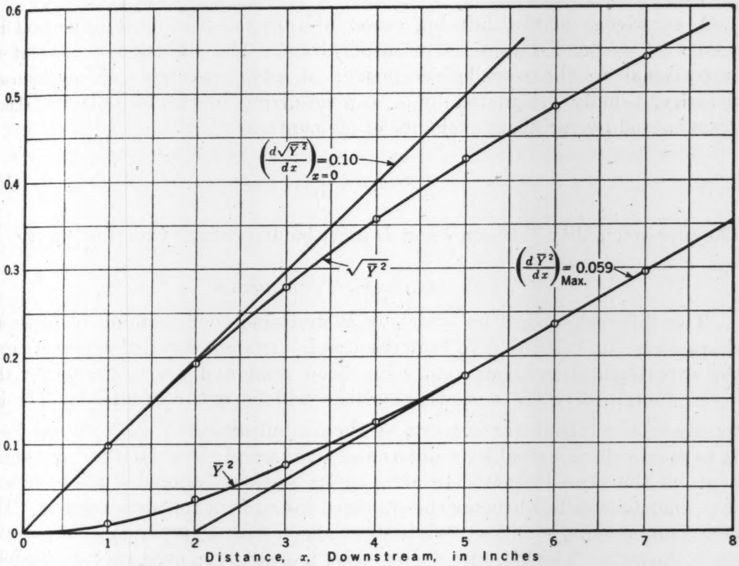

FIG. 6.—EXPERIMENTAL DATA ON DIFFUSION IN A TURBULENT WATER STREAM (Bars Over Squared Terms Indicate the Mean of the Squares and not the Square of the Mean)

A mathematical relationship between $\overline{Y^2}$ and x is not a very convenient means of characterizing the diffusing power of turbulence. A diffusion coefficient would be the logical thing to determine. Using the ideas of molecular diffusion theory, such a coefficient would be defined as:

$$D = \frac{U}{2}\left(\frac{d\overline{Y^2}}{dx}\right)_{\max} \dots\dots\dots\dots\dots\dots\dots (16)$$

The value of $\left(\frac{d\overline{Y^2}}{dx}\right)_{\max}$ for the data in Fig. 6 is 0.059. The dimensions of D are $\frac{L^2}{T}$, or a velocity times a length. The velocity is the root mean square transverse velocity, $\sqrt{\overline{v^2}}$, and the length term is the length associated with mixing processes. This length term is proportional to the size of the turbulent eddies, and to Prandtl's so-called "mixing length."

It should be added that the relative concentration of the color or droplets transverse to the turbulent stream varied according to the normal error curve; that is,

$$N = \frac{1}{\sqrt{2\,\pi}\,\sigma}\,e^{-b\,Y^2} \dots\dots\dots\dots\dots\dots\dots (17)$$

in which: $b = \frac{1}{2\,\sigma^2}$, to simplify typography; and $\sigma^2 = \overline{Y^2}$, so that $b = \frac{1}{2\,\overline{Y^2}}$. The probability that a particle would lie between Y and $Y + dY$ is given by $N\,dY$.

A knowledge of the diffusing power of turbulence is most important in studies of suspended material transportation. The diffusion coefficient is proportional to the so-called coefficient of eddy viscosity, or mechanical viscosity, usually designated by ϵ, and occurring in the formula for shear stress caused by turbulent exchange of momentum:

$$\tau = \rho\,\epsilon\,\frac{dU}{dy} \qquad (18)$$

The proportionality between ϵ and D must be determined experimentally.

Experimental Techniques

The different quantities which it is desirable to determine in order to characterize turbulence have been discussed. A more detailed explanation of the experimental methods that have been used and are available for the determination of these various quantities will be outlined briefly. The intensity of the turbulence is given by the magnitudes of $\sqrt{\overline{u^2}}$, $\sqrt{\overline{v^2}}$, and $\sqrt{\overline{w^2}}$. It is practically impossible to determine all three of these fluctuating components at the same instant. In aeronautics and wind-tunnel studies the hot-wire anemometer has become the standard instrument for measuring $\overline{u^2}$. The cross components, $\overline{v^2}$ and $\overline{w^2}$, can be determined with a special type of hot-wire anemometer.[13] The hot-wire anemometer has not been used very successfully in water, due primarily to difficulties such as collection of air bubbles and other foreign matter on the wire, the extreme magnification of the fluctuating current that is necessary in high-velocity water, and various other troubles. Nevertheless, it has been used in water at lower velocities and undoubtedly will find further use.

One of the most convenient methods of determining simultaneous values of u and v, or u and w, in water, is by studying the motions of particles suspended in the flowing water. If illuminated, such particles make streaks on motion-picture film, and from the length and direction of the streaks two components of the velocity can be determined. Particles made from a mixture of carbon tetrachloride and benzine, having a specific gravity equal to that of water, have been used. The particles are illuminated by a narrow plane of light, so that only those particles in the light are visible.

Another method used by the writer to obtain values of the cross velocity, v, for very short intervals of time, involves a thin color stream injected into the stream through a fine needle. A motion picture was taken of this stream close to the needle. The velocity v for very short intervals of time is obtained by measuring the transverse travel Y for short distances, x, downstream. Distance x is short enough so that the direction of the color stream is practically a straight line. The value of v is then $\frac{Y}{t}$, in which t is $\frac{x}{U}$. A large number of values of v enable the calculation of $\sqrt{\overline{v^2}}$. Such a color stream is shown in Fig. 5. The writer has found that good measurements of simultaneous values of u and v can be made by photographing, with a constant speed motion-picture camera, the travel of the immiscible droplets for a distance of about 1 in. from the point of injection. A magnifying type of close-focusing lens is used on the camera so that a picture is obtained of an area of about 2 sq in. Following the movement of the particles from frame to frame on the film permits the determination of u and v, and if sufficient data are obtained the quantities $\sqrt{\overline{v^2}}$, $\sqrt{\overline{u^2}}$, and $\overline{u\,v}$ can be calculated.

---

[13] National Advisory Comm. for Aeronautics, *Technical Report No. 581*.

Another method of determining $\sqrt{\overline{v^2}}$ is from diffusion experiments, by finding the initial slope of the $\sqrt{\overline{Y^2}}$-curve, as shown in Fig. 6, and using Equation (14). The energy dissipative characteristics are determined by finding a factor proportional to the mean square of the turbulent velocity gradients such as λ, which was defined by Equation (11), or the factor $\overline{n^2}$, as defined in Equation (12). The term λ can be determined by measuring the correlation coefficient R_x, and the term $\overline{n^2}$ is calculated by analyzing the velocity fluctuation at a single point. In air flow R_x is determined by use of two hot-wire anemometers placed a distance x apart. The writer was able to measure R_x by injecting color at two points, a distance x apart, simultaneously, and photographing the two streams together.

The determination of the diffusion coefficient by diffusion experiments has been discussed. Undoubtedly, this is the most direct means of finding the diffusion characteristic of turbulence. Evidence exists that the diffusion coefficient is related to the intensity of the turbulence as given by $\sqrt{\overline{v^2}}$, and the length factor λ. The term λ is proportional to the size of the eddies, and the greater it is, the greater is the diffusion for a given value of $\sqrt{\overline{v^2}}$.

Unquestionably, the photographic method is an accurate and ideal method for making fundamental studies of turbulence in the laboratory. It is time-consuming and tedious, particularly the analyzing of the data recorded on the motion-picture film. An instrument that would give accurate recordings of the instantaneous velocity in a direction either longitudinal or transverse to the flow would be useful. Of course, such an instrument would have to be compared with data obtained by the photographic method in order to insure that it is following the velocity fluctuations accurately and is not introducing turbulent effects of its own. A forward step in the development of such an instrument has been made by C. W. Hubbard,[14] who has developed a so-called "angularity" indicator which measures the mean angle of flow. This angle, of course, is proportional to the mean transverse velocity.

The cup type of current meter is very sensitive to turbulence. However, because of its inertia it does not follow all the velocity fluctuations exactly. It does give some information regarding the magnitude of the velocity fluctuations and the size of the eddies, if the speed of rotation of the vane is obtained, by some automatic recording arrangement, for short intervals of time over an extended period.

RELATION OF TURBULENCE RESEARCH TO HYDRAULICS PROBLEMS

Energy Dissipation.—There are many problems in aeronautics, physics, chemical engineering, and meteorology in which knowledge of the turbulence mechanism is quite important. However, this paper will be confined entirely to outlining some specific problems in hydraulic engineering which could be solved more accurately and more completely with information on turbulence.

Considering the general problem of energy dissipation, there are various individual problems which require a knowledge of the manner in which energy is dissipated. There are some design problems in which it is desired to obtain the maximum energy dissipation possible, and some in which the energy dissipation must be a minimum.

In a conduit of expanding cross section, the additional losses of energy associated with such an expansion are directly attributable to the creation of turbulence energy beyond that ordinarily present in uniform flow. In such an expansion, whether gradual or sudden, there is first an increase in the energy of turbulence and then a decrease.

In order to study the energy transformations completely, the energy of turbulence as given by Equation (5) must be found, in addition to the ordinary kinetic energy, as computed from the average velocity distribution. Fig. 7 shows some typical velocity data as obtained by the method of streak motion pictures in a 3-in. circular pipe. Fig. 8 shows similar data for a section of a 3-in. by 5-in. expansion. The rate of flow in both cases was 0.0818 cu ft per sec. In computing the turbulent energy the transverse velocity component, $\overline{w^2}$, was assumed equal to $\overline{v^2}$; this is quite true for flow in a circular conduit, except very near to the wall. The total mean kinetic energy as obtained from the mean velocity distribution is given by,

$$E_m = \pi \rho \int_0^r y \, U^3 \, dy \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

The total energy of turbulence is

$$E_t = \pi \rho \int_0^r y \, U \, (\overline{u^2} + \overline{v^2} + \overline{w^2}) \, dy \ldots\ldots\ldots\ldots (20)$$

The value of E_m in the 3-in. pipe is 0.255 ft-lb, and E_t is 0.00793 ft-lb. In this case E_t is 3.1% of E_m. The value of E_m in the expansion at the 3.75 diameter section is 0.157 ft-lb, and E_t is 0.0135 ft-lb, or 8.6% of E_m. Note the relatively higher value of the turbulent energy in the expanding portion. Data such as that given in Fig. 8 enable the accurate study of the energy changes taking place from point to point.

Although turbulent energy can be created very quickly, for instance, in a sudden expansion, the dissipation of that energy does not occur immediately. The expression "shock loss" is used many times to describe the energy loss at

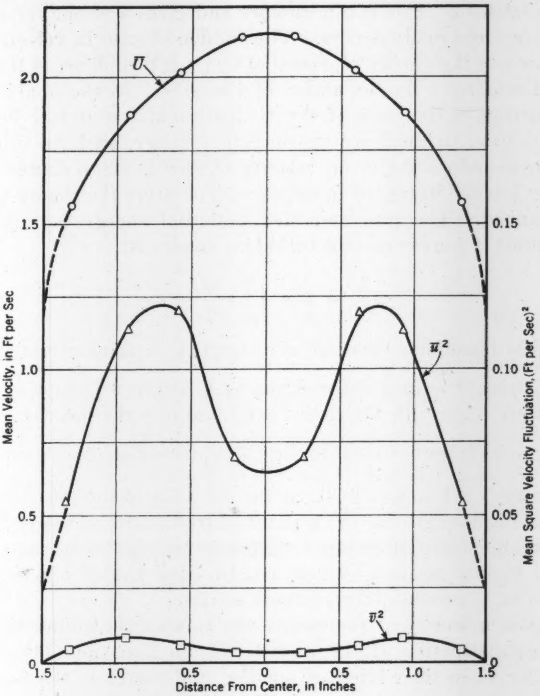

FIG. 7.—VELOCITY DATA FOR A 3-IN. UNIFORM CONDUIT

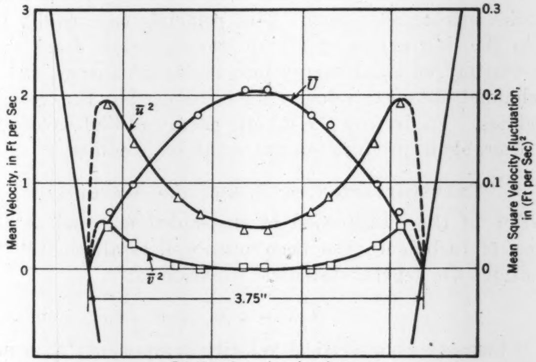

FIG. 8.—VELOCITY DATA FOR A SECTION IN A GRADUAL 3-IN. BY 5-IN. EXPANDING CONDUIT (Bars Over Squared Terms Indicate the Mean of the Squares and Not the Square of the Mean)

a sudden expansion. This is a misnomer and gives a wrong impression as to how the energy loss really occurs. The sudden change in velocity causes extreme turbulence; the energy represented by such turbulence is then gradually dissipated downstream by the action of viscosity. In the final analysis, viscosity, or friction, is the cause of the dissipation of energy into heat.

If it is desired to dissipate considerable energy, such as below dams or spillways, or to reduce the mean velocity of flow in steep chutes or conduits, much can be learned in regard to such problems from the theory of the turbulence mechanism. The rate at which potential energy per unit length of circular conduit is converted into turbulent energy is:

$$Q \frac{h_f}{L} = 2 \pi \int_0^r \tau \frac{dU}{dy} y \, dy \ldots\ldots\ldots\ldots (21)$$

in which: $\frac{h_f}{L}$ = loss of head per foot of conduit; Q = total weight of water flowing in unit time; τ = unit shear stress at y distance from the center; and r = pipe radius. For fully developed turbulent flow the shear stress is equal to $\rho \, \epsilon \frac{dU}{dy}$, in which ϵ is proportional to the diffusion coefficient, or more specifically, to the quantity $\sqrt{\overline{v^2}} \, l$, in which $\sqrt{\overline{v^2}}$ is the intensity of the transverse turbulent velocity, and l is a length factor determined by the size of the eddies. Therefore, the rate of potential energy transformation can be increased, assuming Q constant, by increasing ϵ, which can be done by introducing large-scale roughness so as to produce large, intense eddies.

For a given intensity of turbulence the smaller the eddies the higher the rate of energy dissipation will be, as is seen from Equation (11). The term λ will be smaller when the eddies are smaller, and therefore the average rate of energy dissipation will be greater. Thus, it appears that once the potential energy or mean kinetic energy of flow is in the form of turbulent energy, the dissipation of this turbulent energy can be hastened by the breaking down of the large eddies into smaller ones. This principle can readily be taken advantage of in the destruction of kinetic energy below dams and spillways. Thus, in converting potential energy into turbulent energy, such as for flow in a pipe or channel, the mean velocity can be reduced by the creation of intense large-scale eddies. To destroy the kinetic energy of high-velocity flow below a dam, it is desirable to produce intense, small-scale eddies.

TRANSPORTATION OF SUSPENDED MATERIAL

The relation of the distribution of suspended material to the exchange characteristics of turbulence has been quite well established.[15, 16] For equilibrium conditions the general statistical equation is:

$$\overline{v \, N} = c \, \overline{N} \ldots\ldots\ldots\ldots (22)$$

in which: v = instantaneous vertical velocity component; N = instantaneous

[15] "Review of Theory of Turbulent Flow and Sediment Transportation," by M. P. O'Brien, M. Am. Soc. C. E., *Transactions*, Am. Geophysical Union, 1933, p. 487.

[16] "Experiments on the Mechanics of Sediment Suspension," by Hunter Rouse, *Proceedings*, Fifth International Cong. of Applied Mechanics, 1938.

sediment concentration per unit volume; c = average velocity of fall of single sediment particles in still water; and $\overline{N}$ = mean sediment concentration at any point above the stream bed. The left side of Equation (22) indicates the net transport of material upward by the turbulence, and the right side is the quantity that settles due to gravity. Under equilibrium conditions they are equal. The value of N at any instant can be represented as $(\overline{N} \pm \Delta N)$. Then the value of $v\,N$ at any instant is $(v\,\overline{N} \pm v\,\Delta N)$. It is quite apparent that when v is upward, ΔN will be positive, and when v is down ΔN will be negative, since the concentration of sediment in general increases from top to bottom of a stream. The mean value of $v\,N$ is then $+\,\overline{v\,\Delta N}$, since the mean value of $v\,\overline{N}$ is zero, because the arithmetic mean value of v is zero. The question now arises as to how large ΔN is. This depends on the distance from which the suspended material is brought up or down or, in other words, on the scale of the turbulence or size of the eddies. Introducing a length factor, l, characterizing the diffusing scale of the turbulence: $\Delta N = l\,\frac{dN}{dy}$; and Equation (22) becomes

$$\overline{v\,l}\,\frac{dN}{dy} = c\,\overline{N} \quad \text{(23)}$$

The term $\overline{v\,l}$, which may be called β, is proportional to the diffusion coefficient defined in Equation (16). Whether β is identical to the momentum exchange coefficient, ϵ, occurring in the shear formula, must be investigated experimentally. To date they have been assumed equal, and preliminary investigations indicate that they are identical. Integration of Equation (23) leads to a relation between the unknown sediment concentration, $\overline{N}$, at any point y above the stream bed, and a known concentration, $\overline{N}_a$, at a point a distance above the bottom of a stream or canal:

$$\text{Log}_e\,\frac{N}{N_a} = -\,c\int_a^y \frac{dy}{\beta} \quad \text{(24)}$$

This expression for silt distribution has been checked both in artificially created turbulence and also in natural streams. The term β varies vertically in a natural stream, tending to increase away from the bottom, reach a maximum at about the mid-depth, and then decrease as the surface is approached. However, the exact variation has not yet been determined.

Another important problem regarding turbulence and suspended material is the predication of the actual concentration at some point (for instance, just above the bottom), knowing the composition of the bottom, the various hydraulic factors, such as mean velocity and depth of flow, and the intensity and diffusing power of the turbulence. Such a relation is necessary if the expression for sediment distribution (Equation (24)) is to be of great practical usefulness. The mechanism of the picking up of sediment from the stream bottom by the turbulent eddies merits intensive experimental investigation. However, such an investigation will be of little fundamental value if the intensity and the diffusing power of the turbulence is not determined at the same time.

In the problems of silt sedimentation, the diffusion characteristics of turbulence are also extremely important. To illustrate how the theory of turbulent diffusion can be applied to the sedimentation of silt, two general problems will be analyzed.

Problem 1.—Consider the problem in which sediment is settling in a turbulent stream, and it is desired to know what the silt distribution is at various distances downstream from the point at which settling starts, and at which point the silt distribution is known. The assumption will be made that the turbulence is of such magnitude that most of the silt that reaches the bottom is not picked up again. Referring to Fig. 9, if the concentration at section (1) at a point h_1 ft above the bottom is N_1 units per unit volume for a particular size of silt, what will be the distribution of these N_1 units at some distance downstream? If the particles were weightless in water they would be diffused according to the laws of turbulent diffusion, and their distribution would be according to the normal error curve as given in Equation (17) (with $\sigma^2 = \overline{Y^2}$). In Fig. 9, the point $y = 0$ would be at the height h_1. Then the average concentration at point h_2 at the section downstream will be:

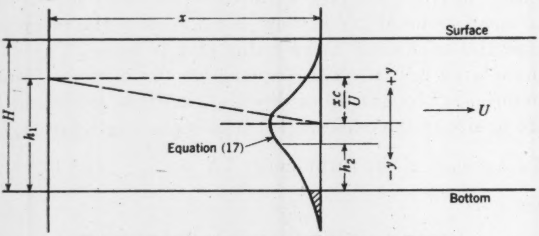

FIG. 9.—SEDIMENTATION IN A TURBULENT STREAM

$$\Delta N_2 = \frac{N_1}{\sqrt{2\,\pi}\,\sigma}\,e^{-b f}\,dy \qquad (25)$$

in which: $b = \frac{1}{2\,\sigma^2}$; $f = (h_2 - h_1)^2$; and $\sigma = \sqrt{\overline{Y^2}}$ = the root mean square diffusion distance as measured from the initial elevation, h_1. If the concentrations N_1 and ΔN_2 are per unit volume, dy can be taken as unity. In words, then, ΔN_2 is the area under the distribution curve between $(h_2 + 0.5)$ and $(h_2 - 0.5)$ times N_1, the concentration per unit volume at h_1. The term $\overline{Y^2}$ is a definite function of x (see heading "Diffusion Characteristics of Turbulence").

Since the silt settles in still water at a velocity of c, it is apparent that the highest concentration (the point on the distribution curve where $y = 0$) will be found a distance of $\frac{x\,c}{U}$ below h_1, or, in other words, the distribution curve will be shifted downward a distance equal to $\frac{x\,c}{U}$. For simplification the velocity U used is the average velocity in the entire stream. The concentration at point h_2 will then be

$$\Delta N_2 = \frac{N_1}{\sqrt{2\,\pi}\,\sigma}\,e^{-b\,i} \qquad (26)$$

in which: $i = \left[h_2 - \left(h_1 - \frac{x\,c}{U} \right) \right]^2$; and (as before) $b = \frac{1}{2\,\sigma^2}$, to simplify topography. To obtain the total average concentration per unit volume at h_2, values of ΔN_2 for all values of h_1, from 0 to H, must be summed:

$$N_2 = \int_0^H \frac{N_1}{\sqrt{2\,\pi}\,\sigma} e^{-b\,i}\,dh \qquad (27)$$

Note that N_1 is a function of h_1 and that h_2 and x are constants for each summation at any one point at section (2). Equation (27) gives the relation between the initial silt distribution and the distribution at another section downstream when settling is occurring.

Problem 2.—The other part of the sedimentation problem is that of finding how much silt settles in a distance x. Of course, the difference between the total concentrations at two points x distance apart is what has settled in the time required for the water to flow a distance x. However, this is a roundabout process of finding the quantity that has settled in the length x; therefore another method is used in finding this quantity. M. A. Velikanov[17] first presented the method outlined herein. The probable quantity of silt that will settle in a distance x from all the silt that passes a point h_1 in a given time is given by the shaded part of the area under the distribution curve, as shown in Fig. 9.

$$(\Delta M)_s = \frac{M_1}{\sqrt{2\,\pi}\,\sigma} \int_{-\infty}^{z} e^{-b\,y^2}\,dy \qquad (28)$$

in which: M_1 = total silt passing a unit area at point h_1 in a given period of time; and $z = \frac{x\,c}{U} - h_1$. The total silt that will settle in a unit time, in the reach x, is then given by

$$M_s = \frac{1}{\sqrt{2\,\pi}\,\sigma} \int_0^H M_1\,dh_1 \int_{-\infty}^{z} e^{-b\,y^2}\,dy \qquad (29)$$

Equation (29) can be simplified, especially if an approximate expression is sufficient. The probability integral can be evaluated readily by reference to books on probability and statistics. However, for the present it is deemed sufficient to present the basic equations only. The next important step is to conduct fundamental experiments in order to check these basic relations.

MISCELLANEOUS PROBLEMS

In addition to the general problems of energy dissipation and suspended material transportation, in which practical application is made of knowledge relating to turbulence, a few others may be stated, as follows:

(1) Many explanations have been proposed in the past as to the reason for the surface velocity in an open channel or stream being less than the maximum.

---

[17] "Theory of Probability Applied to Analysis of Sedimentation of Silt in Turbulent Streams," by M. A. Velikanov, *Transactions*, Scientific Research Inst. of Hydrotechnics, Leningrad, 1936, p. 50.

The fundamental explanation is related to the turbulence mechanism, and more specifically to the process of diffusion of fluid masses in the form of eddies which are formed at the channel boundaries and then diffuse into the main body of the stream.

(2) The relation between high surface-water velocity and the entrainment of air is dependent on the degree of turbulence in the water, which in turn depends on the depth of flow and the channel roughness.

(3) A problem that has recently been studied in detail is that of the relation of the turbulence in a conduit to the accuracy of the Allen salt-velocity method of measuring discharge.[18] In general, the conclusions seem to be that for a high degree of turbulence (that is, for relatively high velocity) the method is more accurate than for slight turbulence. Errors may also result if the measurements are made in a reach of pipe in which the turbulence is changing, such as beyond a bend, valve, pipe expansion, or other turbulence producing device.

(4) Instruments for measuring mean velocity and static pressure in a turbulent water stream are affected more or less by the fluctuating velocities. Current meters, especially those of the cup type, greatly over-register in turbulent water. The velocity head read by a pitot tube is greater than that due to the average velocity depending on the degree of turbulence. The static pressure read by a static-pressure tube placed in a turbulent fluid has a reading greater than the true static pressure by an amount proportional to the mean squares of the cross-velocity components. However, with intensities of turbulence ordinarily present in water conduits or channels, the error in the reading of a well-designed pitot tube or static-pressure tube should be less than 1%.

(5) In conclusion, it should be mentioned that in aeronautics the measurement of the intensity, and the scale of turbulence, is rapidly becoming a standard laboratory procedure in all fundamental experimental work. In the near future, undoubtedly, such measurements will be made part of many hydraulic laboratory investigations. For example, if model studies are made of problems involving energy dissipation or of problems dealing with suspended material transportation or bed-load movement, in order that such studies be fundamentally sound, dynamic similarity must be maintained as far as intensity and scale of the turbulence are concerned. Turbulence should be thought of in terms of definite parameters instead of just as a qualitative descriptive term relating to a general condition of flow.

ACKNOWLEDGMENT

Grateful acknowledgment is given to E. R. Van Driest and to J. M. Robertson, Juniors, Am. Soc. C. E., research assistants, for help in taking and analyzing data. Fig. 18 in the closing discussion was plotted from data supplied by Mr. Robertson in his thesis, "Diffusion Characteristics of Turbulence in an Open Channel," submitted to the University of Iowa in January, 1940, in partial fulfilment of the requirements for the degree of Master of Science.

DISCUSSION

Hunter Rouse,[19] Assoc. M. Am. Soc. C. E. (by letter).—In welcoming the appearance of this latest interpretation of present-day theories of fluid turbulence, one cannot help being impressed by the rapidity with which the modern engineer profits by advances made in related fields of science. It was many decades before hydraulic engineers became fully aware of the value to them of the fundamental contributions of Boussinesq and Reynolds, whereas engineers of today already have before them in a clear, concise form an interpretive summary of the many significant developments made within the last few years. It is particularly fitting that this paper has been written by Professor Kalinske, for he is the first of the hydraulic engineers to have applied these statistical theories in the laboratory to problems primarily hydraulic in nature.

As is evident from even casual study, the readers for whom the paper is particularly intended are those whose efforts may immediately benefit by the adoption of the statistical method of approach—that is, research men seeking to further the science of hydraulics. (As if in illustration of the value of these methods to the research profession, the author, following the preparation of the present paper, collaborated in the application of the statistical approach to the analysis of the amount of material lifted from the bed of a sediment-bearing stream[20]—with results likely to prove of great worth in the ultimate solution of the suspended-load problem.) However, the writer feels that the practicing engineer may also find much of interest in this paper, particularly if he overcomes a natural tendency to let its mathematical aspects conceal the general information which it contains.

In past résumés of turbulence theories, it will be recalled that the subject matter was necessarily restricted to conditions of statistically steady, uniform flow, such as that in circular pipes, the growth of turbulence in an expanding boundary layer receiving only brief attention. The internal mechanism of the turbulence was investigated qualitatively, but only as a means of developing general expressions for velocity distribution and boundary resistance. Although the resulting equations were sufficiently exact for practical use, the qualitative analysis of the turbulence on which they were based was not accurate enough to establish the absolute intensity of the turbulence at any arbitrary point in the flow. That knowledge of this nature has become essential to further progress is shown by the attention now being given to quantitative analysis of turbulence in such widely different fields as meteorology, oceanography, and aeronautics—to which fields that of hydraulics is now added.

For the hydraulic engineer it is no longer sufficient merely to acknowledge the presence of turbulence in uniform circular pipes. He must realize, as Professor Kalinske points out, that such terms as "shock loss" and "impact loss" are definitely misnomers, that all hydraulic losses are ultimately attributable only to viscous dissipation into heat, and that by understanding the formation and subsequent decay of turbulence such losses can be controlled to a great extent. Such an understanding is probably instinctive to many an hydraulic engineer, although on every side one encounters the results of basic misconceptions. For instance, it has been suggested that one must devise a new word to distinguish the large-scale "turbulence" in rivers from the small-scale turbulence in pipes—although the large-scale "turbulence" in question really consisted of local eddies bearing the same relation to the actual turbulence of the river as the eddies at a change in pipe section bear to the normal turbulence of pipe flow. As noted by the author, eddies produced by local disturbances are by no means synonymous with true turbulence. Such eddies, however, are a primary source of turbulence, and the rate of subsequent energy dissipation is a matter of considerable importance. For example, many so-called "energy dissipators" could be made far more effective and less dangerous in their downstream influence if designers realized not only that the formation of large-scale eddies effectively reduces the mean velocity of flow, but also that the presence of such eddies is sometimes as harmful as that of a high mean velocity; as pointed out by Professor Kalinske, the production of intense small-scale eddies (approaching the state of isotropic turbulence) is an essential means of hastening energy dissipation.

[20] "The Relation of Suspended to Bed Material in Rivers," by E. W. Lane, M. Am. Soc. C. E., and A. A. Kalinske, *Transactions*, Am. Geophysical Union, Part IV, 1939, p. 637.

Of primary significance, evidently, is the fact that both the length scale and the velocity scale of turbulence govern the processes of diffusion and energy dissipation. The product of these scales is already familiar to the student of turbulence in the factor ϵ, the so-called "eddy conductivity," previously determinable only for uniform flow, and then only roughly through measurement of velocity distribution and resistance. Professor Kalinske has outlined two methods whereby the length and velocity scales for both uniform and non-uniform flow may be determined individually. He notes, however, that in either method the evaluation of the results is extremely tedious. Several hydraulic laboratories are already on the search for a simpler, and hence more practical, means of accomplishing such measurement in water, but their goal is by no means yet in sight. It is to be hoped that the present paper will also serve as a further incentive to this end.

MARTIN A. MASON,[21] ASSOC. M. AM. SOC. C. E. (by letter).—In an effort to clarify the present status of fluid turbulence research with respect to hydraulics, it seems pertinent to discuss briefly several concepts included in Professor Kalinske's paper, which may be sources of misunderstanding for the practical hydraulicians to whom the paper is addressed.

Unfortunately, much confusion of thought exists on the fundamentally important concept of the nature of turbulence. Among those thoroughly familiar with modern thought on the subject one finds turbulence as a generic term modified as isotropic, non-isotropic or anisotropic, initial, fully-developed, etc., each of which designations indicates to the experienced reader a characteristic phenomenon. To the practical man who is not familiar with the mathematical treatment of turbulence, however, these terms are usually meaningless. For these readers turbulence is a general designation for any or all types of irregular or agitated flow. Ordinarily flow in an open channel is "turbulent," as is the discharge over a dam spillway, the flow through a sluice gate, or the flow behind a bridge pier.

---

[21] Asst. Hydr. Engr., National Hydr. Laboratory, National Bureau of Standards, Washington, D. C.

Obviously, before the hydraulic engineer can benefit greatly from the work of the investigators in the field of turbulence theory consistency of thought must be established as to the nature of turbulence. In this connection, Dryden[22] makes a pertinent comment when he writes, "It cannot be stated too emphatically that the definition of turbulence is necessarily arbitrary and the most useful definition depends on the purpose of the study." Thus, for the purpose of studying the theory of turbulent flow it may be convenient to define turbulence (as Professor Kalinske has done) as being of an entirely random nature without definite periodicity with time, since the mathematical treatment is somewhat simpler for this case. In the case of flow along a boundary, which is the type most commonly encountered by hydraulicians, a more suitable definition of turbulence might be that it is motion such that correlation exists between the fluctuating velocity components at any point in the flow.

The translation of these statistical definitions into terms familiar to the average hydraulic engineer is beyond the scope of this discussion and the writer can emphasize only the importance of the suggestion that the reader not familiar with the concepts outlined consult certain works of Messrs. Dryden,[22, 23] Bakhmeteff, and Rouse.

If the foregoing definition of turbulence is admitted to be the most suitable for hydraulic engineering purposes, it is noted that the present statistical theory of turbulence does not offer immediate possibility of application to most hydraulic problems, inasmuch as it is chiefly concerned with isotropic turbulence. It must be admitted that, for the hydraulic engineer, at present, the statistical method of studying turbulence is only a useful tool which shows promise of being valuable under certain circumstances because of the simplifications it permits. Actually, at the moment, it is of little value for the solution of practical hydraulic problems, and hydraulic engineers should not expect it to supplant some of the older empirical methods of investigation. In this latter class one may cite the remarkable results achieved by L. Prandtl and his students, and by Theodor von Kármán.

Referring to Professor Kalinske's discussion of energy dissipation, it is suggested that, from the hydraulician's point of view, the determination of the time period necessary for the required dissipation of energy in the form of anisotropic turbulence is perhaps more important than the determination of the rate of dissipation. For example, consider the case of a dam spillway; the kinetic energy of the discharging water may be changed rapidly, and in substantial part, to anisotropic turbulent energy in the stilling basin; but, unless this turbulent energy is substantially dissipated in the basin, scour of the downstream bed will result. As shown by Professor Kalinske, the determination of the rate of dissipation of turbulent energy is rather complicated even for the relatively simple case of isotropic turbulence, a condition seldom, if ever, encountered in practice. It would seem certain, however, that (as indicated by the interpretation of the term λ as a measure of the diameters of the smallest eddies responsible for the dissipation of energy[6]) the smaller the size of the eddies the more rapid will be the dissipation of energy, and consequently the smaller the required basin length.

[22] "Turbulence and the Boundary Layer," by H. L. Dryden, *Journal of the Aeronautical Sciences*, Vol. 6, No. 3, January 1939, p. 99.

[23] "Turbulence, Companion of Reynolds Number," by H. L. Dryden, *Journal of the Aeronautical Sciences 1*, No. 2, 67, April, 1934.

As suggested by Professor Kalinske in "Miscellaneous Problems" (No. (5)), model studies involving energy dissipation, sediment transportation, or bed-load movement require that dynamic similarity exist between the intensity and scale of the turbulence in model and prototype. A somewhat related consideration is found in wind tunnel studies where a similarity of turbulence in the tunnel is necessary to obtain comparable results from different wind tunnels. This condition led Dryden to remark[22]

> "* * * the turbulence characteristics of the wind tunnel need to be known and taken into account in the interpretation of measurements. * * * We have to do essentially with a new independent variable whose effects are as important as those of Reynolds number and in many ways similar to those of Reynolds number * * *."

With this latter thought in mind, one may derive from the Navier-Stokes equations (which are applicable to turbulent flow since the velocity components used in the equations refer to instantaneous velocities) not only the usual parameters (Reynolds, Froude) governing the relation of model to prototype; but also, a third parameter having a form similar to Froude's number, which governs the viscous stresses in the two structures. The thought is suggested that this third parameter might be of the nature of a turbulence parameter, whose function is to relate the turbulence in model and prototype.

It should be remembered that similar Reynolds numbers for model and prototype do not alone guarantee similar conditions of turbulence unless there is complete geometric similarity. This may be shown as follows: The cause of the discrepancy in turbulence values in wind tunnels is the effect of the grids or vanes in the tunnel, the turbulence in the tunnel being a characteristic of the grid or vane installation. The corresponding source of discrepancy in hydraulic models would be the stilling racks or basin at the water supply end of the model. If such devices are not similar to those in the prototype, or do not establish flow conditions comparable to those in the prototype, there is no assurance that the intensity and scale of the turbulence in model and prototype are similar even if the same Reynolds number obtains for the two.

The possibility of the existence of a scale effect of turbulence between model and prototype would appear to be sufficiently real to justify the attention of model experimenters in those cases where the turbulence characteristics of the water are important.

Regarding experimental techniques, the writer had the opportunity to develop a method of observation of a stream injected into flowing water which uses fluorescent products illuminated by ultra-violet light.[18] The method shows some promise but has not yet been developed as fully as the excellent technique used by Professor Kalinske. Its principal advantage lies in the fact that the injected stream is seen as a lighted streak on a dark background, thus avoiding the interference of parasitic light reflected from the impalpable particles carried by the water.

In any photographic method employing foreign particles to reveal the motion of the water some uncertainty attaches to the assumption that the added particles truly follow the exact motion of the water particles. This would be true especially when the added particles are of the nature of droplets of an immiscible liquid, unless the droplets are exceedingly small. Similarly, the use of an injected stream of color may be questioned because of possible inertial and viscosity effects. However, Charles Camichel and his co-workers have shown[24] that aluminum particles approximately 0.1 mm in diameter, when washed in alcohol and introduced into a body of water, reproduce exactly the motions of the liquid particles they replace. It would be interesting to compare the magnitude of the droplets used by Professor Kalinske with the size of the particles recommended by M. Camichel.

A photographic method which has been used with considerable success in France for the study of the instantaneous distribution of velocities around a propeller would seem to offer great possibilities for the study of the turbulence problem. First suggested by Marey,[25] developed by numerous investigators, particularly M. Camichel,[26] and in 1937 completely described by M. Chartier,[27] the method is of particular interest because of its applicability to the study of any type of fluid motion in space by stereoscopic means.

In brief, motion pictures are taken of the movement of entrained aluminum particles, utilizing stroboscopic light. A comparison stereopticon of special design is then used in the study of each frame of the film obtained, or the motion may be studied by ordinary projection means. By the use of motion pictures combined with stroboscopic illumination the paths of the illuminated particles over very short time intervals are obtained as a series of dashed streaks, from which the particle velocities may be computed. The minimum interval of time recommended for the stroboscopic illumination is of the order of $\frac{1}{800}$ sec. An improvement of the method, resulting in a considerable saving of time, is the use of a stereo-projector so arranged as to locate the particle streaks on a coordinate system. This arrangement permits the determination of velocities within about 1% error, and the determination of position in space with about 5% error.

J. C. STEVENS,[28] M. AM. SOC. C. E. (by letter).—Professor Kalinske has been continuing the research project "Conversion of Kinetic to Potential Energy in Expanding Conduits" started by Frederic T. Mavis, M. Am. Soc.

C. E., for the Special Committee of the Society on Hydraulic Research.[29] The basic method of approach to this problem has been well set forth in this paper. The author has brought the practical aspects of fluid turbulence home to the hydraulic engineer.

Lately hydraulic engineers have recognized that the energy gradient in tortuous conduits is quite uniform and that energy losses are not concentrated at bends as was long believed. In the light of the author's treatment the explanation is simple: The so-called losses are merely heat dissipation through the viscous properties of water in turbulent motion that continue downstream far beyond the origin of the turbulence. In uniform flow the boundary contacts are a source of continuing turbulence, a balance having been reached between that and heat dissipation. Bends, expansions, and piers are sources of concentrated turbulence, and the heat dissipation from them persists for a long way downstream, thus giving a more or less uniform gradient of energy losses.

The author states (see paragraphs following Equation (21)): "* * * the smaller the eddies the higher the rate of energy dissipation will be." Perhaps this explains why the hydraulic jump is such a potent source of energy dissipation, most of the energy being lost in a comparatively short reach. This must be due to the violent internal eddies set up as a result of the sudden expansion, the visible, foamy, front roller being responsible for only a relatively insignificant portion of the total loss.

The data in Figs. 7 and 8 are of particular significance in explaining why kinetic energy cannot be converted to potential energy without inherent losses. As the author states (see heading: "Turbulence and Energy Considerations"), turbulent energy is a degraded form and is irrecoverable, thus being in broad conformity to the second law of thermodynamics. If, in Fig. 8, the water were caused to flow in the opposite direction, it is likely that the $\bar{u}^2$-curve and the $\bar{v}^2$-curve would become even less prominent than they appear in the uniform pipe of Fig. 7. This feature may be worthy of further investigation.

There is need of means and a method of measuring velocities at any point in a flowing prism without inserting something that itself causes turbulence. Professor Kalinske has solved the problem very cleverly by the use of a motion-picture camera and droplets of an immiscible liquid of the same specific gravity as water. These can be injected into the prism far enough upstream so that the slight turbulence caused by the needle becomes negligible at the camera.

The tedious labor involved in analyzing the data thus gathered, however, is a serious handicap to the method. Perhaps simpler, yet just as effective, means will be found in time.

BORIS A. BAKHMETEFF,[30] M. AM. SOC. C. E. (by letter).—There scarcely can be a subject of greater importance to the hydraulic engineer than the phenomenon of turbulence. Its outward apparent aspects have been known for years. Systematic detailed studies, however, and particularly quantitative appraisal of the inner mechanism, are a matter of recent development. So far, most of the investigations were connected with the aeronautical field. Mr.

[30] Prof., Civ. Eng., Columbia Univ., New York, N. Y.

Kalinske is "breaking ground" in the domain of hydraulics. No praise is too high for this worthy initiative.

In the study of turbulence, as in other domains of physical science, the first requirement is the acquisition of facts—dependable records of actual observation. Observational technique in the domain of turbulence is exceptionally difficult. For air, the present-day needs are satisfied by the hot-wire anemometer, particularly as perfected by the National Bureau of Standards. For liquids, the hot-wire method has not asserted its usefulness; so recourse must be taken to photographing molar movements, rendered visible by that, or other, optical means. The outstanding achievement in the past is the work of A. Fage and H. C. H. Townend. Mr. Kalinske has come forward with new suggestions in this line. The successful development and application of the new technique constitutes, in the view of the writer, the principal contribution of Mr. Kalinske's paper. The experimental curves, as shown, justify the hope that the complex features, specifically characteristic of turbulence as it occurs in hydraulics, may some day really become revealed and elucidated. For the moment one may only regret that Mr. Kalinske did not describe his technique in greater detail.

A drawback of all cinematographic methods is their natural tediousness. For the moment that is an inescapable evil. No greater service could be rendered to the hydraulic profession, than if some ingenious inventor conceived a device that would permit observing and registering turbulence in liquids directly. The problem stands as a challenge, open to competitive imagination.

Mr. Kalinske purports to recapitulate briefly the principal results attained by the statistical method. The achievements of the English school are particularly emphasized. Perhaps the author has tried to encompass too much material into too narrow a space, because the nearly laconic brevity might be found somewhat trying. The paper, on the other hand, should rightly be considered as a pioneer attempt, and the engineer should not feel discouraged by the first encounter with a subject which, in the course of years, is certain to become a familiar every-day tool for whoever will be striving to penetrate and understand the baffling mysteries of the behavior of "water."

So far, the most tangible contributions of the statistical approach are not in the realm of a general all embracing "theory." With all the brilliance in recent advances, the "theory" has not reached the state of lucid certainty, which could make it a useful tool in the hands of the engineer. Statistical treatment, on the other hand, has matured into certain well-established basic definitions, which permit one to appraise and characterize turbulent phenomena in plausible numerical terms. The curves in Mr. Kalinske's paper pertaining to such definitions would seem to indicate the way through which these new concepts can be best conveyed to the "mind" of the profession. No tool is really available until it becomes physically tangible and until its dynamical essence can be explained in the simplest terms. The surest path is to lay open physical facts and make clear their practical meaning and significance. This is the next step to be achieved by the interpreters of the theory.

A question of especial interest is the spatial distribution of turbulent intensity in a cross section. The matter bears directly on efforts to unveil the mystery of the origin and spreading of turbulence. The writer is particularly interested in the form of the $\bar{u}$-curve as given in Fig. 7. As mentioned before, factual knowledge of turbulent phenomena is more than scarce and no opinions of too categorical a nature are warranted at this stage. Nevertheless it does seem that all observations heretofore concur,[31] that the axial component continually increases from the center toward the wall, at least to within the unstable border zone next to the laminar sublayer. The Fage and Townend[32] ultramicroscopic photos show the largest fluctuations as being in the closest proximity (distance less than 0.003 in.) to the wall. More recently such conceptions have been substantiated by observations at the Massachusetts Institute of Technology.[33] They stand, moreover, in close relation to the present-day views on the pendulatory character of the motion in the laminar zone, so admirably elucidated by Dryden.[34]

The writer would like to learn from Mr. Kalinske whether the particular outline of the $\bar{u}$-curve, shown in Fig. 7 (which reaches a maximum at about one half the distance and then declines) has been generally substantiated by repeated observations or may be ascribed to some accidental reason. The point is of vital interest in its possible bearing on the gradually crystallizing conception, that the eddies, which make for turbulence, are principally generated in a special active zone growing out of the instability of the laminar sublayer. Prandtl[35] most aptly characterized this zone as a "vortex mill" (Wirbelfabrik), assuming that the central portions of the fluid, into which the eddies are "cast off," play a more or less passive rôle.

The foregoing remarks tend to show how uncertain, as yet, is current knowledge of the inner mechanism of turbulence. They do not detract in any way from the value of Mr. Kalinske's contribution.

CLYDE W. HUBBARD,[36] Esq. (by letter).—Compliments are due the author on his clear and simple exposition of the theory of turbulence. More and more it is necessary for the hydraulic engineer to study the mechanism of turbulence in the hope that some of the unexplained phenomena of flowing water will become clear.

However, the author states in the conclusion of his paper that: "The static pressure read by a static-pressure tube placed in a turbulent fluid has a reading greater than the true static pressure by an amount proportional to the mean squares of the cross-velocity components." If this were true, the pitot differential would be less than the true velocity head and the coefficient of the pitot tube would be larger than unity. This is contrary to the experience of practically all investigators who have made tests with ordinary types of pitot tubes in pipes.

[36] Asst. Prof., Hydr. Eng., Worcester Polytechnic Inst., Worcester, Mass.

The author also states that the error of a well-designed pitot tube or static pressure tube should be less than 1%. In other words, the customary form of pitot tube can be relied upon to read the true velocity within 1% in the turbulent flow normally found in pipes.

Tests described by the writer[14] and by E. Shaw Cole,[37] Jun. Am. Soc. C. E., in 1939, show that for the ordinary form of pitot tube the error caused by turbulence may be as much as 5% and ordinarily is about 2%. In connection with these tests the intensity of turbulence or "mean angularity" of flow was measured in pipes from 12 in. to 72 in. in diameter at velocities ranging from 3 to 8 ft per sec.

No measurable error in the reading of the impact orifice of a pitot tube was found to be caused by turbulence, which is in agreement with the author's statement. However, turbulence did appear to cause an error in the reading of the pressure head by either a wall piezometer or by a static orifice on the smooth tip of a pitot-static tube. This error in the pressure reading, although important in pitot-tube measurements, was not great enough to affect, seriously, the accuracy of pressure head measurements for pump and turbine efficiency tests.

Mr. Cole[37] describes tests with various simple pitot tubes using carefully constructed wall piezometers made in three 12-in. pipes having different flow patterns. The coefficients obtained for pitot tubes were different in each of the three pipes. Since the impact orifice was found to have no appreciable error, it can only be inferred that the change in coefficient was caused by errors in the wall piezometer readings.

The wall-piezometer error varied with the ratio of mean to center velocity, known as the pipe factor. The error increased proportionately as the pipe factor decreased below unity, so that a coefficient of 0.968 was obtained in the roughest pipe having a pipe factor of 0.77.

The writer described similar tests with a smooth pitot-static tube at the center of the same three pipes in the closure to his paper.[38] The same pitot tube was tested at the center of each of the pipes and the coefficients obtained were 0.992, 0.980, and 0.956. These coefficients, however, did not bear a simple relation with the pipe factor as did Mr. Cole's tests with wall piezometers; nor did the coefficient appear to depend on the intensity of turbulence alone.

It is possible that, when the scale (mean eddy size) as well as the intensity of turbulence are both measured successfully, some rational explanation of the error of the pitot-static orifice will be forthcoming. Near the wall of the pipe both the scale and intensity of turbulence are dependent on the condition of the pipe surface, and any turbulence caused by an upstream disturbance would be dissipated rapidly in the small intense eddies. It would be expected, therefore, that an error of the wall piezometer caused by turbulence would vary with the wall roughness and hence the pipe factor. On the other hand, the turbulence at the center of the pipe is largely of the isotropic type which does not produce shearing stress in the fluid. The scale and intensity of turbulence which exists may be dependent on upstream conditions, since the eddies are larger and the decay less rapid. Therefore, the error of a pitot-static pressure orifice at the center of a pipe, caused by turbulence, would not necessarily bear a consistent relation to the pipe factor or to the intensity of turbulence alone, but may be dependent partly on the scale of turbulence as yet not measured in these pipes.

---

[37] "Investigation of Errors in Pitot Tubes," by C. W. Hubbard, *Transactions*, A. S. M. E., Vol. 61, 1939, p. 495.

[38] *Loc. cit.*, p. 504.

One method of avoiding the effect of the existing turbulence in the center of a pipe on the pressure orifice of a pitot-static tube is to create a disturbance of the flow immediately upstream from it. A small ring was placed on the smooth tip just ahead of the pressure orifice and the tests in the three 12-in. pipes repeated. The coefficients obtained were 0.897, 0.885, and 0.889 as compared with 0.992, 0.980, and 0.956 with the smooth tip. The ring improved the consistency considerably, although the coefficient was decreased.

The test results described herein show that turbulence does appreciably affect the accuracy of pitot-tube measurements and causes the coefficient to be less than unity. However, the pitot tube remains an accurate instrument for flow measurement when properly used by experienced engineers. Errors caused by turbulence can be avoided by the use of a type of tube that is but slightly affected and by calibrating it under flow conditions similar to those under which it is to be used.

JOHN S. MCNOWN,[39] JUN. AM. SOC. C. E. (by letter).—Professor Kalinske has presented several excellent methods of approach to the difficult problem of turbulence, and has substantiated many of his conclusions by laboratory measurements. With so many phases of hydraulics depending on turbulence, the need for study and laboratory research on turbulence in hydraulics has become more and more pressing. This paper gives the fundamental principles, points out the fields of application, and describes the laboratory approach in detail. In addition, an important function fulfilled by this paper is the bridging of the gap between laboratory data and the mathematical theories of statistics and turbulence.

The photographic technique outlined by the author is an improvement over other existing methods for measuring instantaneous velocities in water. Any type of apparatus that must be placed in the water is indeed of doubtful accuracy until proved otherwise. One apparent difficulty with the photographic measurements, in addition to that of analyzing the pictures, is indicated by the angular character of the curve in Fig. 1 which gives the relationship between time and instantaneous velocity fluctuations. An increase in the number of pictures taken per second should smooth out the curve, but would increase the difficulty in analyzing the individual frames.

Several questions arise from the discussion of the quantity λ, defined, following Equation (11), by the formula

$$\lambda = \underset{x \to 0}{\text{Limit}} \left(\frac{x}{\sqrt{1 - R_x}} \right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

and its use in the determination of the energy loss resulting from turbulence.

---

[39] Instr. of Math., Mechanics and Hydraulics, Univ. of Minnesota, Minneapolis, Minn.

The author does not give the conditions under which the data used for this analysis were obtained or the degree to which the isotropy assumed in the development was attained. Furthermore, the method of determining the numerical value of λ is not fully understood by the writer. A knowledge of the functional relationship between x and R_x would be necessary to determine the value of the limit given in Equation (30) as the definition of λ. In a treatment of the same topic in a report by the Fluid Motion Panel of the Aeronautical Research Committee[40] a knowledge of the value of the quantity $\overline{\left(\frac{\partial v}{\partial x}\right)^2}$ is used in computing the value of λ, whereas the author computes λ independently and uses it to compute $\overline{\left(\frac{\partial v}{\partial x}\right)^2}$. The assumption of a parabolic distribution near the peak of the curve, as proposed by G. I. Taylor,[41] would make the reverse order of computation possible. The validity of such assumption depends upon the agreement between the curves at the peak.

The several lengths defined as helpful concepts in the study of turbulent flow must be interrelated to some extent. The concept of the correlation of instantaneous velocities at two points in a stream appears to be closely related to one of Prandtl's two definitions of a mixing length—namely, the diameter of the mass of fluid moving as a whole.[42] A comparison of Prandtl's mixing length, the length λ, the length represented by the x-intercept of the curve in Fig. 3 ($x = 4.6$ in., approximately), or the length criterion defined by Taylor would be interesting if possible. The aforementioned curve in Fig. 3 gives the relationship between x, the distance between two points, and R_x, the correlation between the instantaneous velocities at the two points. The x-intercept of this curve would be the least distance at which no correlation exists.

Among the hydraulic problems affected by turbulence is that of bed-load movement. One troublesome feature of bed-load studies is the lack of unity in interpreting the meaning of "beginning movement," and the application of this concept to other stages. Usually experimenters refer their results to this stage as a basis for computation in using such quantities as excess bottom velocity and effective tractive force. Conceivably part of the difficulty in reaching a common interpretation of this reference stage and the resulting relationships is caused by failing to consider the variable of degree of turbulence. A high degree of turbulence would cause an initial movement at comparatively low values of tractive force as the local velocities are of greater magnitude than for less turbulent streams. Furthermore, this difference becomes less with increasing velocity as the intermediate local velocities become more important. Thus, the effect of turbulence should be investigated in standardizing the results of comparable research problems. A difficulty in such an analysis is the probable absence of isotropy in the turbulence near the boundary where its effect is most important in this problem.

[42] "Hydrodynamics," by H. L. Dryden, F. G. Murnaghan, and H. Bateman, *Bulletin*, National Research Council, 1932, p. 396.

The use of the letter Q to represent weight of water flowing per unit of time is a departure from general hydraulic practice. Too much difficulty is encountered through unavoidable discrepancies in nomenclature without departing from the more or less standard usages. The letter W has been used for this quantity or, more commonly, $Q\,w$.

While questioning these few minor details the writer wishes to concur wholeheartedly with the basic principles presented in this paper. Very important in utilizing this work is a clear understanding of the underlying assumptions and restrictions applied in the derivation of the theory. Much appreciation is due the author for sifting out these concepts from the mathematical theory of turbulence and presenting those topics of most direct use to hydraulic theory and practice.

Samuel Shulits,[43] **Assoc. M. Am. Soc. C. E.** (by letter).—A need in present-day American hydraulics is to convince the so-called practical hydraulic engineer that fluid mechanics is a tool of much promise and not a scientist's toy. It is gratifying that Professor Kalinske devotes himself so capably to this task and that the Society is "blazing the trail."

Significance of the Statistical Fundamentals.—The frequency distribution curve in Fig. 2 is found to conform to Equation (1), the Gauss-Laplace law of frequency of errors, while other investigators are said to have verified this distribution law. Is it not a well-established mathematical law of statistics that deviations from the mean of any large number of measurements will array themselves in this fashion?

Isotropic turbulence is the name given to a flow situation such that $\overline{u^2} = \overline{v^2} = \overline{w^2}$ and $\overline{u\,v} = \overline{u\,w} = \overline{v\,w} = 0$. The physical significance of this mathematical definition may be of interest. Consider the so-called "precision index,"[44] $h = \frac{1}{\sqrt{2\,\overline{v^2}}}$. The larger it is, the more closely do the deviations cluster about the maximum ordinate (of the frequency distribution curve) at which $v = 0$; or the greater is the concentration of the observations about their mean. Since $\overline{v^2} = \frac{1}{2\,h^2}$, the first condition of isotropism merely states that, as a whole, each of the three rectangular velocity components departs from its mean value in the same general way.

If u and v are always of the same sign, $U + u$ and $V + v$ have like trends: $u\,v$ and the mean of the products $(\overline{u\,v})$ are always positive. A value of the instantaneous velocity along the x-axis greater than the mean will be found with an instantaneous velocity along the y-axis greater than the mean; the same applies to sub-average instantaneous velocities. A negative $u\,v$ indicates the coexistence of a sub-average and a super-average velocity along the x and y

[44] "Handbook of Engineering Fundamentals," edited by O. W. Eshbach, John Wiley & Sons, Inc., 1936, pp. 2–124.

axes—that is, an opposite trend of variation. A positive value of the algebraic sum of these products ($\overline{u\,v}$) stands for a like over-all trend of u and v whereas a negative quantity indicates an opposite course. If the grouping of u and v is quite accidental so that there is no relation between them, the sign of the product $u\,v$ will be negative and positive haphazardly and the mean product of a large number of observations will be zero. Consequently $\overline{u\,v} = 0$ denotes that there is no recognizable relation between u and v, as the plus and minus values of the products are collectively of equal weight. Therefore, the nature of u cannot be predicted from v and vice versa, and their relationship is entirely random, which is what one might envisage in the word "turbulence." Thus the second condition of isotropism is simply one mathematical statement of the disorderedness or "mixed-up-edness" of turbulence.

The transformation of the statistical mean product into a non-dimensional criterion results in the correlation coefficient, R_x. If v_1 always equals v_2, $R_x = 1$, whereas if v_1 is always the negative of v_2, $R_x = -1$; but $R_x = 0$ signifies no apparent interdependence between v_1 and v_2—their array (arrangement) is entirely accidental. When v_1 and v_2 are observed at points very close together (within the average size eddy), a close relationship (or correlation) should be expected, so that R_x should be nearly unity as Professor Kalinske states. The smaller x is, the more alike v_1 and v_2 should be, a situation that is easily visualized. On the other hand, the farther apart the points are, the more random should be the mathematical relationship, and the condition of seeming confusion (turbulence) prevails. Thus $R_x = 0$ is merely another parametric statement of turbulence. The physical connotation of Professor Taylor's characteristic scale of turbulence[6] (Equation (4)) follows easily: l' is the distance between two velocities when R_x approaches zero or the disconnectedness of the velocity concepts is absolute. The trend between R_x and x in Fig. 3 is also explainable in the light of the foregoing, although not the exact equation of the curve.

Professor Taylor's premise that "the statistical correlation between the velocity of a fluid mass at one instant and at another later instant is high when the time interval is small, and this correlation approaches zero when the interval becomes large," is an easily accepted physical dictum. The shorter the time interval between two measurements at one point, the more related they might be expected to be and therefore the closer R_t would be to unity. As the interval increases the relation should become more haphazard, and R_t approaches zero. Thus, the fundamentals of the statistical correlation method are used to express physical realities of turbulence.

The Diffusion Coefficient.—The coefficient of viscosity, μ, has the dimensions $\frac{F\,T}{L^2}$, or a unit force times time. In pure viscous flow the unit shearing stress or unit frictional force is completely given by $\tau = \mu \frac{du}{dy}$; but in turbulent flow, there is an additional friction or drag due to the transverse motion of the water particles. By analogy this frictional force has been expressed as $\tau' = \mu' \frac{du}{dy}$

in which μ' is an apparent viscosity. The total unit friction is then as expressed by Equation (7). Since $\mu' = \rho\,\epsilon$ and ρ has the dimensions $\frac{M}{L^3} = \frac{F\,T^2}{L^4}$, then ϵ has the dimensions $\dfrac{\frac{F\,T}{L^2}}{\frac{F\,T^2}{L^4}} = \frac{L^2}{T}$, a velocity times a length, or an area divided by time. Its proportionality to D, the diffusion coefficient of Equation (16), is readily seen. It is really a time rate of change of area and therefore its significance as a measure of transverse diffusion or particle transfer is apparent.

Whither Fluid Mechanics?—From about the middle of the nineteenth century to the present there may be said, without rigid accuracy, to be three phases in the development of hydraulics and fluid mechanics. The first period was a very prolific stage of empiricism (Bazin and Darcy, for example) to which the practical hydraulic engineer is indebted for much of what is still the most serviceable information. Hydrodynamics (Boussinesq and Lamb, for example) existed contemporaneously, but the hydraulician and the hydrodynamist do not seem to have collaborated. The former was prone to regard the latter as impractical and given to making premises not related to the facts. This first phase is still a powerful and indispensable overlapping one, from which modern fluid mechanics will derive much of its basic data.

Then followed a short second phase with Prandtl the leader, in which analogies and imaginative concepts were used, with the results of aerodynamic research as a basis. The main accomplishment was to coordinate and correlate old and new experimental data, with particular emphasis on Reynolds' number and dimensional analysis. Much basic data were gathered.

The present is the beginning of the third phase. As far as fluid mechanics is concerned, the other two periods had not been very fertile of broad theories, although productive of much data. The researchers suddenly realized that the experimental results must be regarded as arrays of fluid mechanics statistics if there was to be order in the research process and in the interpretation and synthesis of the information into basic concepts. The recent statistical theory of turbulence is more accurately the embryonic theories and facts of turbulence examined in the light of the laws of chance or statistics. It is not new theory—only the dawn of orderly research. The shame and wonder is that investigators were so late in their realization of this gross inadequacy in their methods. A debt of gratitude must be expressed to Professor Taylor for impressing the facts forcefully on modern hydraulics and to Professor Kalinske for his masterful applications.

Even the modern hydrologist does not seem to realize that hydrology is a collection of hydrologic facts requiring statistical analysis. There is very little theory to modern hydrology—merely an interpretation of data.

There is a great need for research of the kind Professor Kalinske has accomplished. With the present meagerness and paucity of basic laboratory and field data, statistical methods will avail very little. The statistical theory of turbulence does not obviate the observation and measurement of turbulent phenomena.

Paul Nemenyi,[45] **Esq.** (by letter).—The pioneer work done by Professor Kalinske in the experimental investigation of open channel turbulence and other turbulence problems pertinent to hydraulic engineering will stimulate many research workers to further inquiries. Eventually, it will also help practical hydraulic engineers to obtain a deeper insight into the fluid motion phenomena with which they deal in their daily work.

Of the many problems with which the paper deals, the writer proposes to discuss mainly one: The question of how a high rate of energy dissipation may be attained under various given conditions. The author appropriately distinguishes two main practical problems: (*a*) The disposition of energy dissipators all along a conduit or a channel in order to convert potential energy into turbulent energy, rather than into kinetic energy of the main longitudinal flow—or, in other words, to prevent the developing of large velocities; and (*b*) energy dissipation at the end of a chute to convert kinetic energy of the main flow into the more dispersed form of turbulent energy and into heat—that is, to destroy the large velocities present.

For several years, the writer has been interested in problem (*a*), which is important in the design of fishpasses, timber-floating channels, and sometimes pipes of surge tanks, and is related also to spillway design. He cannot agree with the author's opinion that quantitative turbulence research in its present stage can give suggestions or information relevant to the solution of this problem. The author bases his opinion primarily upon a formula for the rate per unit length at which potential energy is converted into turbulent energy in a circular pipe. The formula may be written in the following form:

$$\text{Rate of energy conversion varies as } \int_{y=0}^{r} \rho \sqrt{\overline{v^2}}\, l \left(\frac{dU}{dy}\right)^2 y\, dy$$

He concludes that in order to secure highly effective transformation of potential energy into turbulent energy, l, the size of eddies (being proportional to l) should be made as large as possible. Even apart from the fact that, as this discussion will show, the reliability of the foregoing energy conversion formula has very substantial limitations, the conclusion of the author is not convincing because in a turbulent flow v and $\frac{dU}{dy}$ are modified as soon as l is modified. All characteristic quantities in the integral being inseparably related, it cannot be decided without further study whether arrangements which produce large values of l would really tend to increase the rate of energy conversion. Indeed, there are good reasons for the assumption that the highest effectivity of energy dissipation can be obtained entirely without resorting to large turbulence eddies.

With little exception statistical inquiries into turbulent flow have been concerned with cases in which the average flow (for a sufficiently long period) is steady, straight, and uniform. The foregoing formula seems to have these limitations. Obviously no rough conduit or channel can strictly satisfy these conditions; and as the size and efficiency of the "roughness" increases, local deviations of average flow from the straight line will also increase in importance. This is one reason for the inadequacy of present-day turbulence statistics in producing a satisfactory treatment of energy dissipators. But even if turbulence research will extend to far more varied phenomena, however, energy dissipation studies will always need to go beyond turbulence study and go back to the more general concept of vorticity, supplemented by such concepts as boundary layers and discontinuity surfaces. The following remarks on the different possibilities of energy dissipation in long conduits will trace (aided by these concepts) the transformation of potential energy into the kinetic energy of the turbulence eddies, thus indicating the conditions under which this kind of energy can be generated at a high rate.

---

[45] Research Fellow, Iowa Inst. of Hydraulic Research, Univ. of Iowa, Iowa City, Iowa.

The first result of such a study is that, the shape of the "roughness" obstacles being given or chosen, the spacing must be recognized as a factor of equal consequence along with the size (height), which many times even today is believed to be the all-important factor. Figs. 10 and 11 illustrate this fact in its simplest and most marked instance. Fig. 10(*a*) shows that obstacles, placed so closely together that only very narrow slits remain between them, fail to disturb the boundary layer to any noticeable extent. In such slits the fluid is very nearly at rest, the pressure being the same as in the undisturbed boundary layer. The "obstacles" have scarcely any measurable energy dissipating influence upon the main flow. (Obviously, the known use of piezometric holes is based on this fact and in certain experiments piezometric holes have been actually replaced by slits in the cross-section direction.) In Fig. 10(*b*) the space between consecutive obstacles is approximately the same as the height of obstacles. The slowly moving material in the boundary layer cannot bridge the gap between the two obstacles; instead the faster moving material from the inner stream transfers some of its momentum to the neighboring fluid in the gap, or "bay." This in turn, by continuity, causes a backward stream near the bottom of the "bay." Thus a vortex, as indicated in Fig. 10(*b*), is generated. However, if, as assumed, the "bay" has a square or nearly square cross section, the vortex is locally fixed (trapped) and stable. As a result, it does not emit vorticity of any considerable amount into the inner stream and remains a poor energy dissipator although the height of the obstacle relative to the total width of the conduit may be very considerable. Only if the Reynolds number computed from the size of obstacle and the velocity of the main flow is extremely high may such a vortex of square cross section become unstable and thus become a more efficient energy dissipator; but no direct experimental evidence is available to support this view.

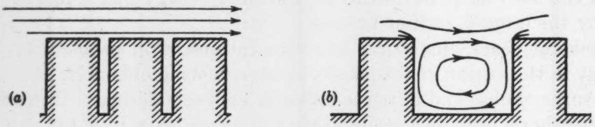

FIG. 10

For longer "bays" the situation is substantially different. Obviously, a very long oval-shaped vortex is unstable; it will give place to a more complex and less stable pattern of flow. Experiments of H. Schlichting[46] indicate, however, that the maximum energy dissipation efficiency of the type of roughness in question is reached only when the spacing of obstacles is approximately ten times their height. To understand this condition better one should first examine the case of the stream field in which there is only a single obstacle upon a smooth boundary. The writer has studied the stream fields experimentally for various shapes of individual obstacles.[47] Figs. 11 (α) and 11 (β) show the results for obstacles extending across the entire breadth of the channel, their cross sections being comparable to those under discussion. (In these figures, the arrows and corresponding numerals indicate velocities expressed as percentages of the undisturbed velocity.) It will be seen that the obstacle deflects the stream considerably, giving to it a momentum toward the inner part of the channel. Thus the region that is the seat of considerable energy dissipation extends far into the inner part of the flow. The lee of the obstacle, on closer investigation, showed velocity fluctuations approaching the same order of magnitude as the local average velocities given in Figs 11 (α) and 11(β). The unsteady part of the vorticity corresponding to these fluctuations is carried far into the inner channel and is the main source of energy dissipation there. If one now wishes to transform (at the highest possible rate) the potential energy all along the channel into such vorticity by the use of perpendicular obstacles, one must obviously place them equidistant, not too far from each other, but far

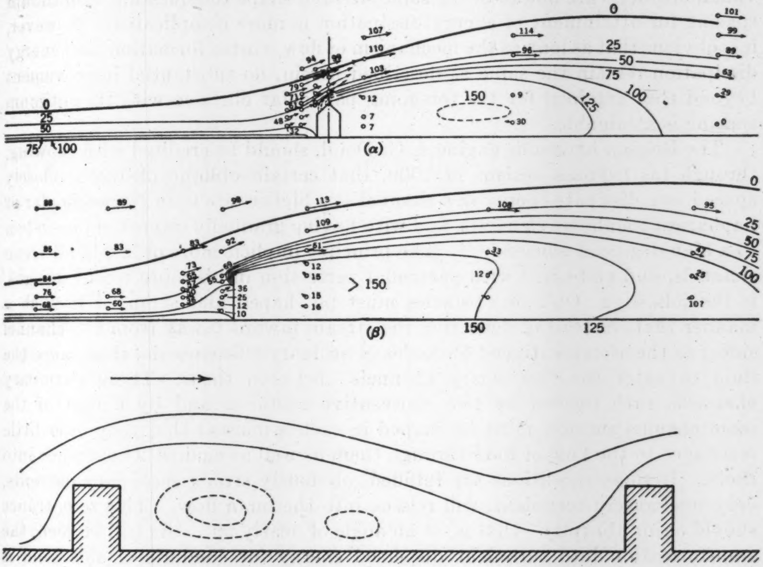

FIG. 11.—CURVES OF EQUAL TOTAL HEAD LOSS

enough to make the development of a considerable forward velocity on the windward side of each obstacle possible (Fig. 11(γ)). Without such a forward velocity the momentum necessary for the development of the large leeward vorticity would not be available. This reasoning explains the experimental finding by Schlichting concerning the optimum spacing. As his results indicate, the order of magnitude of optimum spacing remains roughly the same if, instead of obstacles extending across the breadth of the channel, separate roughness elements such as hemispherical shapes are used. Of course, if the individual obstacles are not all of the same size and shape the question of optimum spacing for attainment of energy dissipation is more complicated. However, it is obvious that as long as the mechanism of flow, vortex formation, and energy dissipation remain the same as described herein, no substantial improvement beyond that attained for the foregoing particular obstacle with its optimum spacing is attainable.

[47] "A New Device for Direct Stream Field Studies and Its Applications," by P. Nemenyi, *Ingeniørvidenskabelige Skrifter No. 39*, Copenhagen, 1935.

The Belgian hydraulic engineer, G. Denil, should be credited with showing, through his fishpass designs of 1909, that certain oblique obstacles, closely spaced, can dissipate energy in a channel at a higher rate than perpendicular or haphazard roughness elements, and with having gradually improved his system to a high degree of efficiency.[48] The principle implicit more or less in all Denil channels, and embodied with particular perfection in his more recent designs, is the following: Oblique obstacles must be shaped and arranged in such a manner that, instead of deflecting the stream inward (away from the channel sides) as the aforementioned obstacles of ordinary efficiency do, they cause the fluid to enter the "secondary channels" between them. These secondary channels, each formed by two consecutive obstacles and by a part of the main channel surface, must be shaped in such a manner that they offer little resistance to the flow of fluid through them as well as against its entrance into them. If these conditions are fulfilled, obviously strong secondary currents, only moderately turbulent, will reissue into the main flow. This re-entrance should occur abruptly—that is, at an angle of nearly 90°. As will be seen, the transformation into turbulent dispersed energy for conduits of this kind is concentrated for the greatest part in the vicinity of the areas where the secondary currents re-entering strike the main flow. In order that the gaps between these areas may be as small as possible, the obstacles should be as thin as practicable.

Since practically all of the designs of G. Denil made for various special purposes are too elaborate to be entirely economical, the writer has endeavored (first in a joint research with C. M. White,[49] and later during his work at the Iowa Institute of Hydraulic Research) to incorporate these principles of energy dissipation into new designs sacrificing as little as possible in efficiency while obtaining considerable simplification. Fig. 12 illustrates three of the designs developed—one of them a result of the London studies, the others of the Iowa studies. (It will be observed that the two latter designs (Figs. 12(*b*) and 12(*c*)) have almost exactly the same kind of baffles, but in one case are adapted to the conditions of a circular pipe and in the other to an open channel with a trough-like cross section.) These simple designs with the directions of flow traced in them well illustrate the foregoing principles of energy dissipation.

White, mimeographed (printed report in *Journal* of the Institution of Civil Engineers is being prepared); see also: "Steep Channels Fitted with Energy Dissipators," by P. Nemenyi, *Transactions*, A. S. M. E., Vol. 60, 1938, Page A-118 (*Journal of Applied Mechanics*).

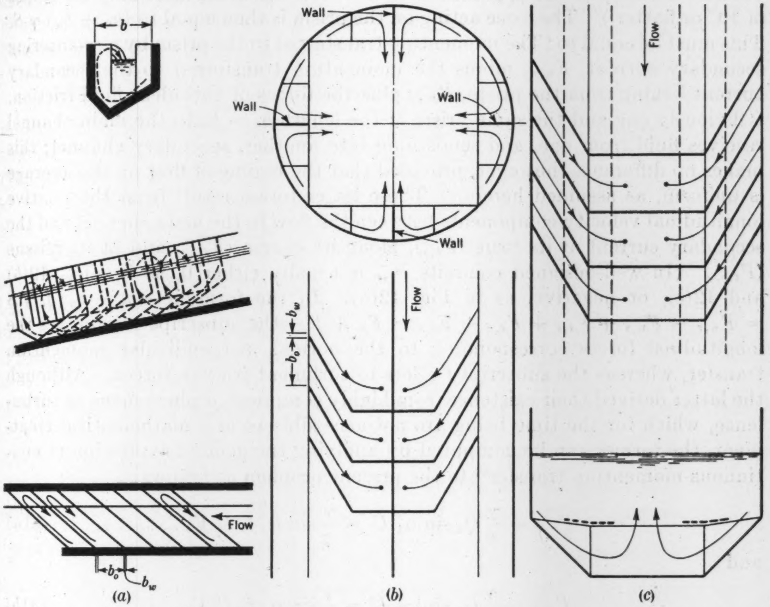

FIG. 12

While testing these and similar fishpasses the writer found the following quantitative explanation for the high effectiveness of this type of energy dissipating device. Suppose the free width of one secondary channel, measured in the direction of the axis of the main channel, is b_0; the wall thickness of secondary channels (measured in the same manner) is b_w; then $b_0 + b_w$ is the spacing of obstacles along the main channel. Applying the momentum theorem to a fluid prism (Fig. 13) of length $b_0 + b_w$ and of cross section f_0 corresponding to

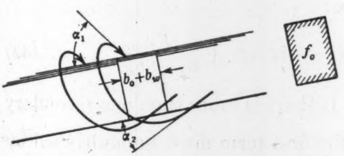

FIG. 13

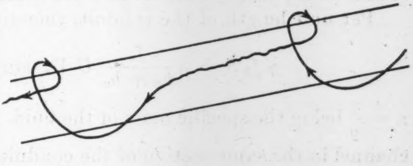

FIG. 14

the inner channel (free cross section), let S be the slope of the main channel, or the pressure loss per unit length if a closed conduit is being studied. (More exactly: $S = \sin \alpha$, in which α is the angle of the channel axis with the horizontal. The use of the approximation $S = \tan \alpha$ is acceptable only for slopes of 10° or flatter.) The force acting on the prism is then equal to $(b_0 + b_w) \gamma S$. This must be equal to: The momentum transferred to the prism by a re-entering secondary current, $F_{n,r}$; minus the momentum transferred to the secondary current issuing from the prism, $F_{n,i}$; plus the forces of turbulent fluid friction. (Obviously one and the same prism of the length $b_0 - b_w$ in the main channel receives fluid from one, and sends fluid into another, secondary channel; this makes no difference, however, provided that the regime of flow on the average is uniform, as assumed herein.) These latter forces result from the relative longitudinal velocity components between the flow in the main channel and the secondary current at its issue ($F_{t,i}$), along its course ($F_{t,c}$), and at its reissue ($F_{t,r}$). (In well-designed conduits $F_{t,r}$ is usually either 0, as in Figs. 12(*b*) and 12(*c*), or negative, as in Fig. 12(*a*). In the formula—$(b_0 + b_w) f_0 \gamma S = F_{n,r} - F_{n,i} + F_{t,i} + F_{t,c} + F_{t,r} = F_n + F_t$—the subscript n indicates the longitudinal forces corresponding to the normal, perpendicular momentum transfer, whereas the subscript t refers to turbulent friction forces. Although the latter derived their existence from highly complicated phenomena of turbulence, which for the time being are not accessible to any mathematical treatment, the former can be computed by applying the general expression of continuous momentum transfer[60] to the present problem as follows:

$$F_{n,r} = \frac{\gamma}{g} Q_s \sin \alpha_1 U = \frac{\gamma}{g} \sin \alpha_1 f_s U V_s \qquad (31a)$$

and

$$F_{n,i} = \frac{\gamma}{g} Q_s \sin \alpha_2 U = \frac{\gamma}{g} \sin \alpha_2 f_s U V_s \qquad (31b)$$

in which g = gravitational acceleration; Q_s, V_s, f_s = rate of flow, average velocity, and normal cross section of the secondary channel; U = average longitudinal velocity of the flow in the main (free) channel section; α_2 = angle of entrance from the main channel into the secondary current; and α_1 = angle of reissue of secondary current into the main channel.

Per unit length of the conduit, therefore:

$$\gamma f_0 S = \rho \frac{f_s}{b_0 + b_w} U V_s (\sin \alpha_1 - \sin \alpha_2) + \frac{F_t}{b_0 + b_w} \qquad (32)$$

$\rho = \frac{\gamma}{g}$ being the specific mass of the fluid. If there is more than one secondary channel in the same section of the conduit the first term must be multiplied by their number, n. (In Fig. 12(*b*), $n = 8$; in Fig. 12(*c*), $n = 2$.)

Theoretical considerations, as well as experimental facts, indicate that the first term is much larger than the second, for a well-designed channel. The structure of this first term contains much of what is essential for the understanding of this system of energy dissipation, particularly if it is compared with the corresponding, well-known formula for channels or conduits of ordinary type.

---

[60] For a graphic explanation of this simple, fundamental relation, see "Mechanics of Turbulent Flow," by Boris A. Bakhmeteff, Princeton University Press, 1936, pp. 38–39.

For a prismatic fluid body in the free cross section of the channel, with cross section f_0, and of unit length, it is generally accepted that in smooth channels as well as in rough channels of the usual types the following relation (a generalized form of Equation (2)) is valid:

$$\gamma f_0 S = \rho P_w \overline{u\,v} \qquad (33)$$

in which: P_w = "wetted perimeter" of the prism; u = fluctuation of longitudinal velocity; and v = velocity fluctuation perpendicular to the perimeter. (For each point of the wetted perimeter the average of $\overline{u\,v}$ for a long period of time must be computed; the quantity in Equation (33) is the average of these averages over the entire wetted perimeter.)

In the light of the remarks at the beginning of this discussion, it is known that Equation (33) cannot possibly be strictly correct for rough channels, because of the deviation of the average velocity vectors from straight parallel lines. For very large roughnesses this deviation may be quite considerable. It can scarcely be doubted, however, that the formula remains correct in so far as orders of magnitude are concerned. (Otherwise the numerous applications of this formula to rivers and other considerably rough conduits could not have led to favorable results.) Therefore, accepting the formula and comparing it with the formula of the highly effective energy dissipators discussed, one finds that in the latter the product of the velocity fluctuations is replaced by that of actual average velocities. On the other hand the entire wetted perimeter P_w of the prism is replaced by the expression $\frac{n\,f_s}{b_0 + b_w}(\sin\alpha_1 - \sin\alpha_2)$ which obviously corresponds only to a moderate part of the wetted perimeter, in accordance with the fact that the generation of turbulence eddies in such energy dissipators is restricted to part of the perimeter. However, this is a factor of lesser order of magnitude than the replacement of a fluctuation-product-average by a product of two average velocities. Thus, it is readily understood from the comparison of the two different mechanisms of momentum transfer that even the simplest of these energy dissipator designs (Fig. 12(*a*)) makes possible slopes, for a given limited average velocity, about 8 to 10 times larger than perpendicular obstacles of the same height with their optimum spacing would permit.

The results of intense momentum transfer produced by the energy dissipators discussed can well be compared to a shock or impact, in contrast to an abruptly expanding conduit, for which—as the author rightly points out—the expression "shock loss" is quite unsuited. Therefore, where the secondary current strikes the main flow, immediately intense but fairly fine-scale turbulence eddies are produced, without the intermediate stage of large-scale eddies. One could be tempted to speak of a large-scale regular vorticity with longitudinal axis; but it is doubtful whether this point of view would be either adequate or fruitful because the path of any individual particle is composed of two quite different kinds of paths alternating with each other in the manner indicated schematically in Fig. 14. It appears that no system of reference in uniform translation movement can be defined with respect to which the movement of the particles would have a closed orbit, and therefore the concept of vorticity is not strictly applicable to the phenomenon as a whole. Furthermore, the high rate of energy dissipation could not be explained by the presence of a vorticity with longitudinal axis, since it is known from other investigations that vorticity of this kind does not dissipate energy of any amount worth mentioning. For example, it is known that the secondary currents, assumedly connected with turbulent flow in a straight, smooth conduit of non-circular section, do not dissipate energy to any considerable extent.

Much more helpful in the understanding of the highly efficient roughness types discussed herein is the concept of "discontinuity surfaces." To be sure, discontinuity of velocity distribution in the strict sense of the word is impossible in any steady phenomenon. Suppose, for example, that a drainage channel meets a river at a certain angle, and that there is a sluice at the channel's mouth. In the instant when the sluice is lifted there is a genuine discontinuity between the velocity distribution in the channel and in the river, and in Fig. 15 line *A B* represents the surface of discontinuity. Quickly upon the generation of eddies, however, and their migration into the main stream, a kind of unity between the two velocity fields is established, no surface of discontinuity (in the strict sense of the word) being present; yet in a more or less narrow strip —tentatively indicated in Fig. 15 by shading—the transition between the velocity distribution of the channel and the river is particularly steep. Such regions of steep transition between two distinct velocity distributions can be represented schematically by a surface or, in the section, by a line of discontinuity; and it is in this sense that "discontinuity surfaces" are discussed in theoretical fluid mechanics.

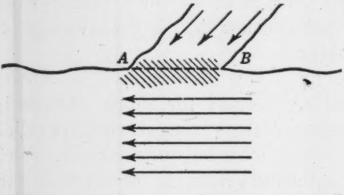

FIG. 15

There are obviously four extreme possibilities for the nature of such discontinuities, and the writer has represented them in Fig. 16 (the dots indicate streamlines perpendicular to the plane of the drawing). Actually any superposition of these cases can occur, but it is valuable to distinguish the distinct fundamental possibilities.

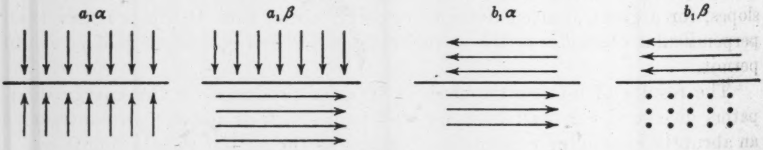

FIG. 16

Where the secondary current "strikes" the main flow, obviously, case $a_1\beta$ is realized with very good approximation. The foregoing momentum transfer studies explain the superior energy dissipating ability of this kind of discontinuity. The writer has made a little experiment with the channel in Fig.

12(*c*) to compare "discontinuity" $a_1\,\beta$ with $b_1\,\beta$. Obviously, in the middle section of each secondary current, its relation to the main current is very close to that in $b_1\,\beta$. Therefore, if this part of the baffles is covered by a longitudinal strip of thin steel sheet as indicated by a broken line in Fig. 12(*c*), the friction term $F_{t,c}$ is replaced by the known and extremely small friction of water upon a smooth steel surface. The comparison has shown that this does not, to any considerable extent, alter flow conditions in the main channel, thus indicating the complete lack of significance of the term $F_{t,c}$ compared with the total force, or with F_n which constitutes its main part. Similar relations can be expected to exist also between the energy conversions corresponding to these various forces. There are indirect reasons for believing also that "discontinuity" $b_1\,\alpha$ is a rather poor energy converter compared with $a_1\,\beta$. Indeed if one looks once more upon the ordinary roughness in its optimum spacing (Fig. 11(γ)), one will find that between the inner flow and the flow within the lee region of the obstacles a steep transition is occurring which can be represented schematically by a discontinuity surface of type $b_1\,\alpha$; and one can conclude from the comparatively moderate efficiency of this type of roughness that this type of "discontinuity surface" is not highly effective as a dissipator of energy.

The writer intends also to examine case $a_1\,\alpha$ by a comparative study of conduit design Fig. 12(*b*) with and without the four straight, longitudinal walls. Obviously these prevent occurrence of "discontinuity" of the kind $a_1\,\alpha$, thus securing secondary currents of greater intensity at the reissue into the main flow. These reissuing jets being of decisive importance for the energy dissipation in the conduit as a whole, the amount of increase in the dissipation caused by the walls will give an indication of the importance of the energy-dissipating effect of a discontinuity of type $a_1\,\alpha$.

It appears on the whole that the concept of "discontinuity surfaces," although an artificial abstraction, is, along with the general concept of momentum transfer, a fruitful aid in the analysis and understanding of the varied phenomena of energy conversion in conduits.

As to problem (*b*), that of destroying the large forward velocities present at the foot of an overfall dam or a chute, the writer fully agrees with Professor Kalinske's remark that, for security against scour or other destruction, transformation of forward flow into large-scale eddies or vortices is not sufficient and that disintegration into a finer-scale turbulence is indispensable. The writer believes, however, that the means to this end will have to be investigated experimentally and that it must be discussed in terms of general momentum transfer and "discontinuity" concepts. Although there are many valuable hydraulic research studies for special structures for scour prevention at the foot of dams, it appears that no general investigation of the problem from this fundamental point of view has been attempted thus far.

The difficulties of the problem are great and manifold. If compared with problem (*a*), discussed previously herein, two additional difficulties will be noticed immediately: First, that problem (*b*) is one of essentially non-uniform flow; and, second, that high-velocity shooting flow must be dealt with. Every experimenter knows the "evasive" character of such flow. Coming from a reservoir or river, the flow in problem (*a*) is relatively slow and can be easily deflected into the secondary channels; water shooting at high velocity is much more difficult to divert.

Nevertheless the writer believes that some of the considerations outlined in this discussion, concerning case (*a*), can well be utilized in case (*b*).

From an excellent study by Schoklitsch[51] it is known that the phenomenon of a "hydraulic roller" connected with the hydraulic jump should be considered as a backward flow of the sluggish water on top of the forward shooting flow, with a "discontinuity surface" between, rather than a single large vortex. From the foregoing comparative discussion it is known, however, that this particular kind of "discontinuity surface" is not one of very high energy dissipating efficiency, and this indicates that future studies may yield very substantial progress by revealing facts concerning "discontinuity" of the kind $a_1 \beta$ shown in Fig. 16. If the writer understands its function, the "jet breaker" ("stralkyvare") suggested by Erik Lindquist,[52] M. Am. Soc. C. E., appears to be an energy dissipator that produces a similar effect.

However, when considering the problem of destroying large forward velocities, it should be kept in mind that the task is not always best solved by dissipating energy at a particularly high rate—that is, by maximum velocity destruction per unit length of structure. It may be more advisable, in many cases, to dissipate the energy at a somewhat more moderate rate, if it can be located conveniently. Therefore it is not impossible that the structures generating an ordinary "hydraulic roller" will be used also in the future since they conveniently solve problem (*b*) by placing the dangerous vorticity, issuing from the discontinuity surface, well above the bed surface.

The writer believes that the most important field for the civil engineering applications of turbulence statistics lies in the problem of sediment transportation in canals and rivers. An entire series of Swiss investigations by aid of the bed-load trap[53] as well as the combined theoretical and experimental research of H. A. Einstein and G. Polya[54] seems to indicate that even the movement of the heavy bed load is essentially connected with the haphazard fluctuation-phenomena characteristic of turbulence. Nevertheless, it would be a fallacy to conclude that the problem of propelling granular materials by fluids can be treated, as a whole, as a problem of turbulence statistics, in the sense that Professor Kalinske makes use of this method. Paradoxically, although the bed-load movement obviously derives its energy from, and shares much of the properties of, the turbulence movement in the higher layers of the rivers, it also shows regular rhythms in many instances (such as shown not only by sand waves, but also, for long periods, by the generation of serpentines). This paradox will probably not find its complete clarification before turbulence will be understood in its relation to regular rhythmic vortex distributions on one hand, to momentum transfer by "grain bombardment" on the other. (The vortex theory of sand waves was first presented by G. Darwin and later developed by Vaughan Cornish[55] and the Swedish School of Geomorphologists.[56] The impact theory of sand waves has been presented by R. A. Bagnold in a long series of publications;[57] although the decisive importance of this factor is limited to Æolian phenomena [desert sand, etc.] it can scarcely be doubted that it must be included among the factors governing fluvial sand propulsion too.) With reference to the river problem the author's inquiries into open channel turbulence must be considered a great step forward to a far-off but very worth-while goal. The methodic aspect of the problem as a whole has been analyzed by the writer in a recent paper.[58]

Finally, a few words in regard to the problems of gathering experimental data for the statistical study of turbulence: This question consists really of two parts—(1) how to make fluid particles visible, and (2) how to record the movement of particles made visible. To problem (1) the author has contributed a highly reliable technique. It should be stated that the ingenious ultramicroscopic method of A. Fage and H. C. H. Townend[32] does not require the addition of any strange material, the very fine suspensions present in drinking water being sufficient in many cases; for macroscopic visibility of air particles Mr. Townend[59] has suggested that it can be attained without strange admixture, but by localized heating through electric flashes combined with the "Schlieren technik"; the method is very interesting although it is rather unlikely to have any direct applicability for water.

The second half of the experimental problem consists of how to record the movement of particles made visible. The writer would like to call attention to L. Prandtl's suggestion[60] that a uniformly moving camera be used with speeds of systematically varied magnitudes. Mr. Prandtl showed how photographs taken with this method can lead to a very convenient system of velocity-fluctuation statistics. The writer should like to add the suggestion that such photographic records can be used for measuring vortex sizes. The camera moving at the speed corresponding to the average velocity of a certain longitudinal strip of the channel, the vortices in this particular strip will appear in their real size. The vortex size distribution in each strip found by this direct method should be compared with the corresponding average vortex sizes. These can be computed according to Mr. Taylor's suggestion[6] from the velocity data, as shown for the open channel by the author.

BENNIE N. NETZER,[61] JUN. AM. SOC. C. E. (by letter).—The practical hydraulic engineer's need has been for someone to put into actuality Mr. Kalinske's statement (see heading "Transportation of Suspended Material") that "Turbulence should be thought of in terms of definite parameters instead of just as a qualitative descriptive term relating to a general condition of flow." Many hydraulic model studies have been made of problems involving energy dissipation, for example, which have had as their net result only comparative indications of the intensity of turbulence, but no quantitative conclusions. The reason for this has been the lack of an instrument for measuring, accurately, the highly fluctuating velocities in turbulent flow.

For a thorough understanding of the turbulence mechanism it is undoubtedly necessary to use some such method as the photographic method suggested by Mr. Kalinske. For quick, practical results, however, some other method that is less time-consuming and tedious and has more flexibility than the photographic method seems desirable. It is difficult to see how the photographic method can be used to measure velocities throughout an entire turbulent region with any ease and without consuming too much time. Model studies involving the analysis of turbulent flow in many hydraulic designs require a quick, practical way for measuring velocities.

Mr. Kalinske states (see heading, "Experimental Techniques") that "An instrument that would give accurate recordings of the instantaneous velocity in a direction either longitudinal or transverse to the flow would be useful." For the determination of the intensity of turbulence in a practical manner such an instrument is necessary.

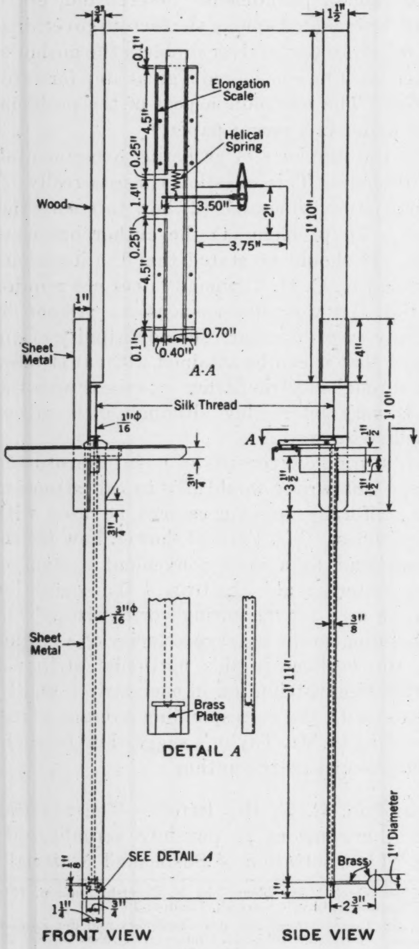

Fig. 17

Fig. 17 shows an instrument that may fulfil Professor Kalinske's requirements. The instrument was designed by H. A. Thomas, M. Am. Soc. C. E., and was used by the writer in experimental work on erosion below dams.[62] The instrument is a helical spring dynamometer that is very sensitive to turbulence and will measure the instantaneous maximum, mean, or minimum velocities at any point in a region of turbulent flow. The meter is essentially a vertical rod, encased in a streamlined tube, with a slightly cupped disk attached to its lower end by a horizontal arm. The torque caused by a current of water impinging on the cupped disk is transmitted by the rod to a horizontal pointer which is restrained in its rotation by two pins. The torque caused by the water current is balanced by a helical spring attached to the pointer and to a slide which moves at right angles to the pointer. When the torque is balanced, the pointer is free of both pins (similar to a scale beam), thus indicating the mean velocity. To ascertain the instantaneous maximum or minimum velocities the spring is stretched until the pointer is just moved from either pin. By suspending the vertical rod by a light thread its weight is removed from the bearings and friction is reduced to an absolute minimum. The instrument is calibrated by measuring the velocity of a jet of water moving with uniform velocity, and then determining the elongation of the helical spring in the same jet.

A. A. KALINSKE,[63] ASSOC. M. AM. SOC. C. E. (by letter).—The writer appreciates the many encouraging comments made by the various discussers, and especially the suggestions and advice submitted by experienced hydraulic engineers. These suggestions will serve as guides for further investigations in this field. Professor Rouse, who has given much thought to various theoretical and experimental phases of the turbulence problem, summarizes in a concise manner the items in the paper which relate to hydraulics problems. His effective analysis of the main features of the paper should prove helpful in dispelling fears that prospective readers may have regarding the presence of the more or less complicated mathematical formulations.

Verbal and privately written comments, other than the published discussions, seemed to indicate to the writer that many hydraulic engineers had the idea that the various theories and analyses presented in this paper had for their purpose the displacement of past ideas on water flow and the demonstration that various practical rules now in common use were all wrong. Nothing could be further from the truth. A study of the inner mechanics of fluid flow and attempts to understand the phenomena of turbulence have for their purpose the providing of basic, generalized information. It is hoped that such fundamental information will permit the bringing together of many apparently different hydraulic problems and will show that there is much that is common among them. Of course, some of the things that will be learned about turbulence will perhaps have no direct practical application. Much of such information will merely provide a better physical picture of the mechanics of turbulent flow. However, there are hydraulic problems for which an increased knowledge of turbulence is vital to their ultimate, complete solution. The recognition of the practical importance of the various conceptions regarding turbulence that were presented is evident in the remarks of the discussers.

---

[62] "Erosion Below Dams," by Bennie Netzer. Thesis presented to Carnegie Inst. of Tech., in 1938, in partial fulfilment of the requirements for the degree of Master of Science in Civil Engineering.

[63] Asst. Prof., Univ. of Iowa, Iowa Inst. of Hydraulic Research, Iowa City, Iowa.

Mr. Stevens states that: "In uniform flow the boundary contacts are a source of continuing turbulence, a balance having been reached between that and heat dissipation." This is a significant and fundamental fact regarding the origin and dissipation of turbulence. Professor Bakhmeteff submits some very pertinent remarks relating to this phenomenon. There is no question but that the boundary regions in a straight conduit are the major source of the turbulence. The writer ventures the opinion that the physical law controlling the creation and shedding of the eddies from the viscous boundary layer in smooth conduits, and from the roughness projections in rough conduits, may some day be formulated. Professor Bakhmeteff raises the question relating to whether the intensity of turbulence is generally distributed across a conduit as shown by the writer's data. Repeated observations in smooth circular conduits by the writer and others have indicated definitely that the longitudinal component of the turbulent velocity fluctuation tends to reach a maximum in the region between the wall and about two thirds the distance from the center.

The writer appreciates the importance of having the proper fundamental concepts regarding the type of turbulence one is talking about, as was shown by Mr. Mason. True turbulence is probably best defined as being motion in which there is no periodicity in the fluctuation in magnitude of the three velocity components, v, u, and w. From a practical standpoint turbulence is nonisotropic if there is a mean velocity gradient normal to the direction of flow. Mr. Mason says that the present statistical theory of turbulence does not offer an immediate possibility of application to hydraulics problems since it is concerned chiefly with isotropic turbulence. This is not entirely true. One of the most important practical hydraulic problems depending for its complete solution on a better knowledge of turbulence is that of sediment transportation. Application of the concepts arising from the statistical theory has enabled the writer to study the mechanics of the placement of sediment into suspension in the bed region of rivers. Certainly the turbulence in this region is far from being isotropic. From the experimental standpoint, application of Professor Taylor's statistical theory of turbulent diffusion[41] has permitted the direct measure of the coefficient of diffusion in an open channel (see Fig. 18). A study of this coefficient is all-important in problems involving the transportation of suspended material. In general, so far as hydraulics is concerned, the statistical theory of turbulence has not provided and probably will not provide for a long time a direct and exact solution to any practical problems. However, it has provided and will provide tools with which hydraulic engineers will be able to get a better insight into the physical phenomena, and also will provide a basic framework from which orderly research can proceed.

Mr. Mason notes various other photographic techniques that have been used and suggested for studying turbulence. The size of the suspended immiscible liquid particles used by the writer averaged about 1 to 2 mm. It appeared that particles of this size were small enough for studying the diffusion and intensity characteristics of the turbulence in the main body of flow in pipes or channels. Studies near the boundary region require the use of much smaller particles, and a magnifying lens system is necessary for taking pictures in this region.

Mr. McNown mentions that the turbulence must be considered in the study of sediment transportation as bed load. This is also pointed out by Mr. Nemenyi in his discussion. There can be no doubt that this is true, and fundamental studies of bed-load movement will have to give consideration to parameters which describe the turbulence quantitatively. Probably one of the most urgently needed fundamental experimental investigations in regard to sediment transport is a study of the zone near the bed where bed material is picked up and transported in suspension. Increased knowledge regarding this transitional zone in the bed region will be the key to the ultimate solution of the problems of prediction of the absolute concentration of suspended sediment. Professor Rouse has stated that:[64] "* * * analysis of the sediment problem as a whole will first become possible when bed-load and suspended load can be expressed as functions of the same flow parameters." In other words, the flow characteristics that control the movement of material along the bed also control the development of the turbulence that is responsible for the placement of material in suspension from the bed region.

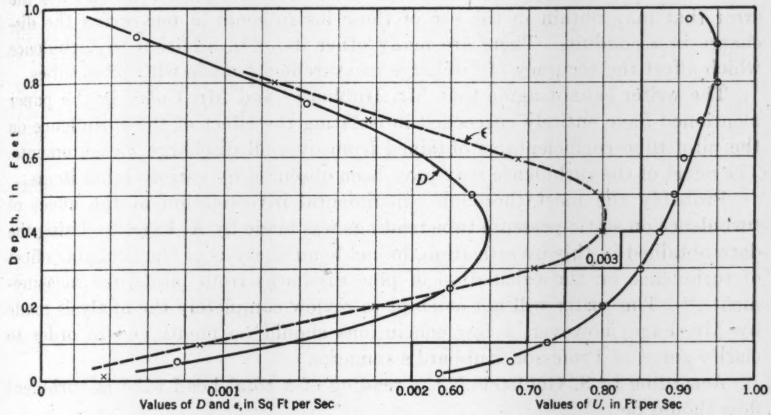

FIG. 18.—VARIATION OF D, ϵ, AND $\overline{U}$, IN THE CENTER OF A SMOOTH CHANNEL

The calculation of the length term λ, which is defined by Equation (30) in Mr. McNown's discussion, was made by substituting in this equation values of R_x for small values of x. This is in accordance with the procedure followed by Professor Taylor.[65] A knowledge of the functional relationship between x and R_x is not necessary in order to calculate λ to a degree of accuracy commensurate with the accuracy of the experimental data.

In the paper the writer makes a brief statement regarding the effect of turbulence on the measurement of static pressure in turbulent flow and the measurement of mean velocity by means of a pitot tube. From some measurements made by himself and various studies by others he concluded that for the ordinary turbulence present in pipe or channel flow the error in the "reading" of a static pressure tube or pitot tube due to the turbulence should not be greater than about 1%. Professor Hubbard, in his discussion, disagrees with this view. First of all it should be emphasized that the writer was talking about the error in the "reading" of a static-pressure tube or a pitot tube and not the error that may obtain in the use of these instruments in measuring the discharge in a conduit. There are many other items in addition to turbulence which affect the accuracy of discharge measurements made with pitot tubes.

---

[64] "An Analysis of Sediment Transportation in the Light of Fluid Turbulence," by Hunter Rouse, U. S. Dept. of Agriculture, Soil Conservation Service, *Technical Publication No. 25*, July, 1939.

[65] "Statistical Theory of Turbulence," by G. I. Taylor, *Proceedings*, Royal Soc. of London, Vol. 151A, 1935, p. 456.

The writer cannot agree that Mr. Hubbard[14] and Mr. Cole[37] in the paper mentioned have entirely succeeded in isolating the effect of the turbulence on the pitot-tube coefficients as obtained from over-all discharge measurements. The effect of the turbulence may have been obscured by various other items.

Probably the most thorough experimental investigation of the effect of turbulence on static-pressure tube readings was made by A. Fage.[66] Using the data obtained in this investigation, he made an analysis of the probable effect of turbulence on the calculation of pipe discharge from pitot-tube measurements.[67] The writer will not attempt to review completely the analysis made by Mr. Fage; however, a few conclusions should be mentioned in order to clarify some of Professor Hubbard's remarks.

According to S. Goldstein,[68] the reading of a total head tube in turbulent flow should be

$$H = \bar{h} + \frac{\bar{U}^2}{2\,g} + \frac{\overline{q^2}}{2\,g} \qquad \text{(34)}$$

in which $\overline{q^2} = \overline{u^2} + \overline{v^2} + \overline{w^2}$, the sum of the mean squares of the turbulent velocity components along the three coordinate axes; $\bar{h}$ is the local mean static pressure head; and U the local mean velocity. Mr. Fage points out that according to the vorticity transport theory the value of $\left(\bar{h} + \frac{\overline{q^2}}{2\,g}\right)$ is constant across the turbulent wake behind a body placed in a fluid stream. At the edge of the wake where the stream is undisturbed the static pressure is equal to $\left(\bar{h} + \frac{\overline{q^2}}{2\,g}\right)$. This indicates that the true local static pressure varies across a turbulent wake. These conceptions are extended by Mr. Fage to the turbulence in a pipe, the main body of the turbulent stream corresponding to the turbulent wake. The reading of a static-pressure tube placed in a turbulent fluid, according to Mr. Fage's investigation, is equal to $\bar{h} + K(\overline{v^2} + \overline{w^2})$, in which K is an experimental constant which will depend on the design of the tube used. However, in any case the reading will tend to approach the value of the pressure at a smooth wall, h_w.

If the pitot tube reads a pressure equal to that given in Equation (34), and the other side of the differential gage is connected to a wall piezometer, Mr.

---

[66] "On the Static Pressure in Turbulent Flow," by A. Fage, *Proceedings*, Royal Soc. of London, Vol. 155A, 1936, p. 576.

[67] "The Estimation of Pipe Delivery from Pitot-Tube Measurements," by A. Fage, *Engineering*, Vol. 145, June 3, 1938, p. 616.

[68] "Measurement of Total Head and Static Pressure in Turbulent Streams," by S. Goldstein, *Proceedings* Royal Soc. of London, Vol. 155A, p. 570.

Fage arrives at the following expression for the fractional overestimation of pipe delivery:

$$\int_0^1 \frac{\overline{q^2}}{\overline{U}_m^2}\left(\frac{\overline{U}_m}{\overline{U}}\right) d\left(\frac{y}{r}\right) + \int_0^1 \frac{(\overline{h} - h_w)}{\overline{U}_m^2/2\,g}\left(\frac{\overline{U}_m\,y}{\overline{U}\,r}\right) d\left(\frac{y}{r}\right) \ldots\ldots (35)$$

in which: $\overline{U}_m$ = mean velocity in cross section; y = distance from center; and r = pipe radius. Professor Hubbard's conclusion that if, as the writer states, a static pressure tube has a reading greater than the true static pressure by an amount proportional to the cross-velocity components, the coefficient of a pitot tube will be greater than unity, is erroneous. The effects of turbulence tend to make the coefficient of a pitot tube less than unity. By various transformations Mr. Fage reduces Equation (35) and gives as an approximate expression for the percentage of overestimation: $\frac{190\,\tau_0}{\rho\,\overline{U}_m^2}$, in which τ_0 is the wall shear and ρ is the fluid density. The maximum value of the expression occurs at the lower Reynold's numbers and is about 1.0%.

In addition to the effect of turbulence, Mr. Fage shows that an overestimation of discharge results from pitot-tube readings due to the fact:

> "* * * that the total head registered by a pitot tube in a region of total pressure gradient is not associated in general with the geometric center of the mouth of the tube, but with an effective center which is displaced from the geometric center towards the region of higher total head."

However, this correction should ordinarily not exceed 0.5% except when a large tube is used in a small pipe. Another item that may influence the reading of a static pressure tube is the deflection of the stream lines of the average flow by the presence of the tube in a region of high velocity gradient—that is, near conduit walls.

Everything considered, Mr. Fage's studies should not be considered as the final word in regard to the effect of turbulence on the readings of pitot tubes and static-pressure tubes; however, his analyses appear to be fundamentally sound and indicate the factors that must be studied in any experimental work on this particular problem.

In his discussion Mr. Shulits wonders whether it is a law of statistics that deviations from the mean of any large number of measurements will be distributed according to the normal error law. This is not true since, if (for instance) the fluctuations were periodic, the distribution of the deviations would certainly not be according to the error law. The fact that velocity fluctuations in fully developed turbulent flow are distributed according to the normal error law is a definite characteristic of turbulence, and not just a mere coincidence or the general behavior of any fluctuating quantity

Mr. Shulits states that the eddy viscosity, ϵ, which is proportional to the coefficient, D, as defined in Equation (6), is a time rate of change of area. Professor Taylor[6] definitely shows that the diffusion coefficient is proportional to the product of the root-mean-square of the transverse velocity and the distance a mass of fluid travels before the correlation coefficient between the velocity at the beginning and at the end of the distance is zero. To state that this coefficient is a time rate of change of area has no physical significance and is merely a "play" on the dimensions of this quantity. The kinematic viscosity, ν, of fluids has the same dimensions as ϵ or D—that is, $\frac{L^2}{T}$. A mere knowledge of the dimensions does not permit a physical interpretation of ν. However, analysis of the physical processes by which, for instance, a gas exhibits the property of viscosity, definitely shows that ν is proportional to the product of the mean velocity of the gas molecules and their mean free path. Professor Taylor's analysis gives a similar physical significance to the quantity ϵ or D.

Experimental data on the variation of D and ϵ in the center of a smooth open channel, 1 ft deep and 2.5 ft wide, are shown in Fig. 18. The mean velocity in a vertical section is 0.865 per ft sec. Values of D were obtained from data similar to those shown in Fig. 6 and ϵ was computed from the relation:

$$\tau = \rho\, \epsilon \frac{d\bar{U}}{dy} \qquad (36)$$

The computation of ϵ was not very accurate since some assumptions had to be made regarding the value of the shear. Nevertheless, the proportionality and perhaps even the equality between D and ϵ are evident.

The writer agrees with Mr. Shulits that the statistical theory of turbulence does not in any way obviate the necessity of observations and measurement; however, it does give direction to such research work.

Mr. Nemenyi makes a very worthy contribution in regard to the retardation of flow in conduits having various types of boundary obstacles. He remarks that energy dissipation studies will have to go beyond turbulence study and into the concepts of vorticity, boundary layers, and discontinuity surfaces. This is true, but it should be added that turbulence studies in general must also go back to these concepts. Since turbulence tends to originate at boundaries and surfaces of discontinuity, the laws controlling the creation of vortices will have to be studied if hydraulic engineers are to learn more about the physical processes in regard to the origin of turbulence. Mr. Nemenyi's remarks relating to the various types of surfaces of discontinuity that may be produced are very enlightening.

Present knowledge seems to point to the fact that ordinary turbulent flow in conduits is the result of the dispersion of eddies from the boundaries into the main body of the fluid stream. Their origin, whether from a surface of discontinuity at the viscous boundary layer in smooth conduits or from roughness projections in rough conduits, is probably governed by strict physical laws. The behavior of an individual eddy in the main fluid stream, of course, is unpredictable.

In order to retard the mean forward velocity of flow in a uniform conduit having a given hydraulic gradient and cross section of flow, the total rate of pressure or potential energy conversion must be decreased. This total rate of energy conversion per unit length of conduit is equal to $Q \gamma S$, in which Q is the discharge, γ the specific weight, and S the hydraulic slope. According to Equation (21), this rate of conversion for ordinary turbulent flow in a circular conduit can be represented by $2\pi \int_0^r \rho\,\epsilon \left(\frac{d\overline{U}}{dy}\right)^2 y\,dy$. The relation between ϵ and $\frac{d\overline{U}}{dy}$ is expressed by Equation (36). The average shear will remain constant if the cross section of flow and S remain the same. Any change in ϵ should result in a proportionally equal and opposite change in $\frac{d\overline{U}}{dy}$. From the foregoing expression for pressure energy conversion (see Equation (21)) it is seen that an increase in ϵ will result in a decrease in Q, or in the mean velocity for a given cross section. In other words, to reduce the mean forward velocity it is necessary to secure intense mixing between the slowly moving water at the boundary and the water in the center portion. This can be done by an increase in the diffusion coefficient, ϵ.

Ordinary roughness projections, as pointed out by Mr. Nemenyi, are not effective for producing a large retardation of the forward velocity. Specially designed obstacles that forcibly throw the water at the boundaries into the main portion of the stream are much more effective in retarding the mean forward velocity of the stream. Though the flow in such special conduits is obviously not directly comparable to ordinary turbulent flow, nevertheless the general concept that intense transverse mixing must be obtained, if a large reduction in forward velocity is to be secured, is still applicable.

In his discussion of the application of the theories of turbulence to problems of sediment transport, Mr. Nemenyi states that it is paradoxical that various regular phenomena manifest themselves in turbulent streams in which the velocity fluctuations are supposedly irregular. Difficult as it may be to imagine how irregular fluctuations can create regular phenomena, nevertheless it does appear that turbulence may even have a direct influence in the production of such effects as for instance the formation of sand ripples on a river bottom. In a paper[69] published in 1939 M. A. Velikanov gives a mathematical analysis which seems to indicate that a plane sand bottom in a uniform stream is transformed into a rippled one by the direct action of the turbulence of the stream.

In regard to Mr. Netzer's comments on the measurement of fluctuating velocities in model studies it should be kept in mind that the photographic methods, as used by the writer, have many advantages even if they are time-consuming. Since no apparatus is introduced into the stream, there is definite assurance that the results obtained are not influenced by, or are peculiar to, the measuring apparatus. Furthermore, the investigators obtain a definite mental picture of the turbulence, which is often as important as the actual quantitative measurements. The time required in analyzing the data obtained on motion-picture film can be shortened by utilizing the principles of random sampling theory. Nevertheless, any instrument, capable of measuring even approximately the turbulent velocity fluctuations directly, would be useful. A checking of the measurements obtained with an instrument such as that shown in

---

[69] "Formation of Sand Ripples on the Stream Bottom," by M. A. Velikanov, *Question 3, Report 13*, published for meeting of International Geophysical Assoc., September, 1939, Washington, D. C.

Fig. 17, against data obtained by photographic studies, would indicate how the instrument responds to the velocity fluctuations in turbulent flow.

It should be mentioned that excellent data on velocity fluctuations in large streams can be obtained with current meters, especially with those of the smaller type. Although, to a certain extent, the data are qualitative, they nevertheless permit the study of the relative magnitude of the velocity fluctuations under different conditions. One of the problems in which a knowledge of the magnitude and frequency of the velocity fluctuations in natural streams is of importance is in suspended material sampling. Before suspended material can be determined accurately and economically, it is important to know how the concentration fluctuates; this fluctuation in sediment concentration is closely allied with the velocity fluctuations of a turbulent stream.

SEWAGE DISPOSAL PROJECT OF BUFFALO, NEW YORK

BY SAMUEL A. GREELEY, M. AM. SOC. C. E.[1]

WITH DISCUSSION BY MESSRS. C. A. HOLMQUIST, ARTHUR J. BULGER, C. R. VELZY, THOMAS M. NILES, AND SAMUEL A. GREELEY.

SYNOPSIS

The purpose of this paper is to make of record, with proper explanation, some of the engineering data accumulated during the design and construction of the sewage disposal project of Buffalo, N. Y. During the three years 1936 to 1939, the Buffalo Sewer Authority completed the construction of intercepting sewers, sewage treatment works, and storm-water relief sewers, at a total project cost of $15,000,000. The sewage disposal works were placed in operation toward the end of June, 1938.

GENERAL STATEMENT

The Buffalo Sewer Authority was created by a special act of the Senate and Assembly of the State of New York and became a law April 8, 1935. The five members of the Authority were first appointed in June, 1935, and later in the year, on December 7, the Authority appointed the organization which was to serve as designing and supervising engineers. Meanwhile, on June 18, the Authority made application to the Federal Emergency Administration of Public Works for a loan and grant, in the amount of $15,000,000, to aid

> "* * * in financing the construction of a system of trunk, intercepting and connecting, lateral and outlet sewers, storm water drains, pumping and ventilating stations, disposal or treatment plants or works, and other appliances and structures to provide an effectual and advantageous means for relieving Niagara River, Buffalo River and Lake Erie from pollution by the sewage and waste of the City of Buffalo and relieving the City of Buffalo from inadequate sanitary and storm water drainage and for the sanitary disposal or treatment of the sewage of the City of Buffalo."

The estimates of cost in this application included construction work in the sum of $13,200,000, and a sum of $1,800,000 to cover preliminary expenses, land and right of way, engineering, interest during construction, legal, and

NOTE.—Published in October, 1939, *Proceedings*.

[1] Greeley & Hansen, Chicago, Ill.

administrative costs. The proposed storm-water relief sewers were for the Bird Avenue Sewer District only.

The first investigation of the sewage disposal problem of Buffalo was made between 1909 and 1918 by the International Joint Commission in connection with an investigation of the pollution of boundary waters. The conclusions stated in their final report are briefly summarized as follows:

> "It is advisable to consider the Niagara and Detroit Rivers as a class by themselves, so far as remedial and preventive systems are concerned. As has been stated, the most serious condition existing is the bacterial pollution of these streams. To remedy this evil, sewage treatment should be applied in connection with dilution so far as is necessary to bring their waters to the standard mentioned—a mean annual cross-sectional average of B. coli not exceeding 500 per 100 c.c. This necessary sewage purification can be effected by fine screening or sedimentation, and when necessary by chemical disinfection, at a cost which will impose no unreasonable burden upon the urban community responsible for the present pollution."

Furthermore, it has been clear for a number of years that the waterways within the city limits of Buffalo have been grossly polluted, including Buffalo River, Buffalo Harbor, and Black Rock Harbor. The function of the sewage disposal part of the project, therefore, is threefold, as follows:

(*a*) To relieve Buffalo River and its immediate tributaries from undue pollution;

(*b*) To relieve Buffalo and Black Rock Harbors from undue pollution; and,

(*c*) To remove contamination from Niagara River and to reduce the bacterial content of its waters in order to avoid placing an undue pollutional load on water purification works of communities below Buffalo which derive their water supply from the Niagara River.

A number of the existing sewers had also been overloaded and much in need of relief. As this was especially true of the existing sewers in the Bird Avenue District, it was decided to include storm-water relief sewers for this sewer district in the project.

Action for undertaking the project was stimulated by the orders of the New York State Department of Health, issued in March, 1934, which required that during 1935 the City of Buffalo must engage engineers, take steps to acquire land on which to construct sewage treatment works, submit plans for the Bird Avenue storm-relief drains, and make a satisfactorily comprehensive general plan for interception and treatment of the entire sanitary sewage of the city. Detailed plans and specifications for a substantial part of the work were required to be completed by April 1, 1936, and construction work started on or before July 1, 1936. The order required that the treatment works be completed and placed in operation on or before October 1, 1937.

Actual construction work was begun on a part of the Bird Avenue storm-water relief drains in December, 1935, and a contract for borings, which ultimately required the expenditure of about $38,000, was started in January, 1936. The first major construction contract went into actual construction in June, 1936, under bids which had been advertised on April 23, 1936. An average monthly rate of construction was maintained during twenty-two consecutive months (from August, 1936, through May, 1938) of $547,000.

FIG. 1.—GENERAL PLAN OF SEWAGE DISPOSAL PROJECT

The City of Buffalo, New York

Buffalo is situated along the eastern shores of Lake Erie and the Niagara River (see Fig. 1). The southern part of the city is cut by the Buffalo River which extends from the harbor in a southeasterly and easterly direction. Much of the area tributary to Buffalo River is occupied by industries, and this is the principal manufacturing district of the city. Scajaquada Creek flows in an east and west direction through the northerly part of the city and is used to form Park Lake in Delaware Park. The northerly part of the city is much more residential in character. The population of Buffalo by the United States Census Bureau, and its estimated probable growth, is as follows:

Year	Population	Year	Estimated population
1840	18,213	1940	670,000
1850	42,261	1950	765,000
1860	81,129	1960	860,000
1870	117,714	1970	955,000
1880	155,134	1980	1,050,000
1890	255,664	1985	1,100,000
1900	352,387		
1910	423,715		
1920	506,775		
1930	573,076		

The total area in 1930 was 26,980 acres and the density of population was 21.3 persons per acre. It was thought likely that the area of the city might be extended somewhat to the north and east in the distant future with the larger populations, but this does not influence the plans. The length of the city in a north and south direction is 8.6 miles and the width in an east and west direction is about 5 miles.

The average temperature and precipitation at Buffalo are indicated in Table 1 which is a summary of data from the U. S. Weather Bureau. The Weather Bureau also reports that the prevailing winds are southwesterly except during November, December, and January, when westerly winds prevail.

Existing Sewers

Practically all the sewers of Buffalo are on the combined plan, their total length being about 710 miles. The first sewers were built prior to 1850;

during the 5-yr period prior to 1855, 23 miles were constructed; and in the 5-yr period prior to 1895, 139 miles were built. Thus, the existing sewers of Buffalo have been in service, in general, for many years. At present (1939) there are about 62 outlets, all of which have now been connected to the new intercepting sewers.

The city is divided topographically into two parts, one draining naturally to the Buffalo River and the other directly to Black Rock Harbor and the Niagara River. With a few exceptions, the main drainage system has developed along these natural lines. In the area north of the lower part of the Buffalo River, a system of canals formerly connected with the old Erie Canal. Some of the city sewers discharged into these canals, which have been covered over and serve as storm overflow sewers. Except in the case of District VII (see Fig. 1), the sewers of Buffalo are on the so-called combined system, with sewage and storm water carried in the same sewers. In District VII the dry-weather flow is confined in part to a separate system of sewers and conducted to the Hamburg Street Pumping Station. This station contains a steam power plant with three horizontal, centrifugal pumps, driven by steam engines. It was formerly operated in conjunction with a refuse incinerator, which has not been used in regular operation since before 1929.

Conditions in the harbor, the canals, and the Buffalo River became objectionable at an early date, and to alleviate this pollution, the so-called Swan Trunk Sewer was built in 1883. This sewer, with a later extension, runs roughly parallel to the Buffalo River and the harbor from Bailey Avenue to Albany Street, where it passes under Black Rock Harbor to the Niagara River. It is 8 ft in diameter for most of its length, and was designed as an intercepting sewer to receive the dry-weather flow from all the area north of Buffalo River and south of the Bird Avenue sewer district. It also receives the discharge of the Hamburg Street Pumping Station. In later years it has been much overloaded and, especially near the upper end, overflows have been frequent or sometimes continuous during dry weather. The capacity of this sewer is utilized in the new intercepting sewer system.

The population and industries adjacent to Buffalo River have continued to discharge their sewage into the sluggish waters of the river. Nearly all the large industries along Buffalo River have private sewers directly to the river.

There are several small areas, chiefly in small separate municipalities, outside the present city limits which discharge sewage into the Buffalo sewers, amounting in the total to about 1,000 acres, with a population of about 13,000.

The characteristics of the major sewer districts of Buffalo are as shown in Table 2.

WATERWAYS

The waterways of Buffalo pertinent to the sewage disposal project are (see Fig. 1): Niagara River, Buffalo Harbor, Black Rock Harbor, Buffalo River, Cazenovia Creek, and Scajaquada Creek.

Niagara River.—The drainage area of the Niagara River, at the outlet of Lake Erie, is about 175,000 sq miles. Based on records of the U. S. Lake Survey, the average discharge is 203,000 cu ft per sec. A discharge of 176,000 cu ft per sec is exceeded 90% of the time. The minimum monthly average discharge of record (142,000 cu ft per sec) occurred in February, 1934; and the maximum discharge (251,000 cu ft per sec) occurred in June, 1876. Thus the discharge is relatively large and uniform.

The elevation of the water surface of the Niagara River opposite the sewage treatment plant on Bird Island covers quite a range. It is estimated that an elevation of − 9.7 (Buffalo City Datum) is exceeded on the average for 99% of the time and an elevation of − 5.7 is exceeded for only 1% of the time. Extraordinary fluctuations in the level of Lake Erie cause momentary peaks in the water level in the river at Bird Island much higher than the foregoing. Thus an elevation of + 2.0 is reached, on the average, once in three years, and an elevation of + 5.0 has an estimated frequency of occurrence of once in fifty years.

* Mgd = million gallons daily. † Gcd = gallons per capita per day.

Below Buffalo, the Niagara River is used as a water supply by Tonawanda, North Tonawanda, Lockport, Niagara Falls, Youngstown, and Fort Niagara, in New York, with a total population of about 150,000, and by the cities of Fort Erie and Niagara Falls in Canada. There is an increasing use of the water for recreation, including boating, fishing, summer homes, and some bathing, mainly limited, at present, to the Canadian shore and to the westerly shore of Grand Island. The average number of B. coli per cubic centimeter at the Niagara Falls water-works intake was 36.7 in 1936 and 27.5 in 1937, with individual samples as high as 240. The analyses of the Sewer Authority laboratory show as great a concentration as 2,400 B. coli per cu cm in the most contaminated sections of the river downstream from Buffalo. The lowest content of dissolved oxygen found during the river surveys of the Buffalo Sewer Authority in July, 1936, was 6.0 ppm.

Buffalo Harbor.—Buffalo Harbor is made artificially by breakwaters in Lake Erie. Little sewage is discharged directly into Buffalo Harbor and it has not been an important factor in the design of the project.

Black Rock Harbor.—On the other hand, Black Rock Harbor has received a considerable quantity of sewage and was seriously polluted. In fact, it is a waterway connecting the New York State Barge Canal with Buffalo Harbor and is relatively long and narrow, having the shape more of a canal than of a harbor. Its length is 16,500 ft, the area of an average cross section is 8,800 sq ft, its surface area is 8,100,000 sq ft, and it has a liquid volume at mean depth of 140,000,000 cu ft. Some circulation (about 100 cu ft per sec) is maintained by the operation of a small outlet at the lower or northerly end of the harbor and by operation of the lock. Variations in the level of Lake Erie also have a marked effect in mixing relatively unpolluted lake water with the harbor water, especially in the upper or southerly end.

The principal source of pollution of Black Rock Harbor was the Bird Avenue outlet which discharged about 25.0 mgd of sewage into the harbor about 3,000 ft south of its lower end. This is about 20% of the sewage of the entire city. An indication of the effect of this pollution is given by the data in Table 3.

Buffalo River and Cazenovia Creek.—Buffalo River and its main tributary, Cazenovia Creek, have a drainage area of 436 sq miles. There is no continuous record of gagings of the quantity of water flowing in Buffalo River. However, the U. S. Geological Survey has a record of routine gagings on Cattaraugus Creek, the drainage area of which is adjacent to that of Buffalo River and includes 488 sq miles. Using the Cattaraugus Creek gagings as a basis, the discharge of Buffalo River has been computed as follows:

Period	Discharge, in cubic feet per second
Annual average	650
Average from May 1 to October 31	355
Annual median	340
Median from May 1 to October 31	180

A discharge of 100 cu ft per sec is exceeded 90% of the time for the year as a whole, and for the period from May 1 to October 31, a discharge of 80 cu ft per sec is exceeded 90% of the time.

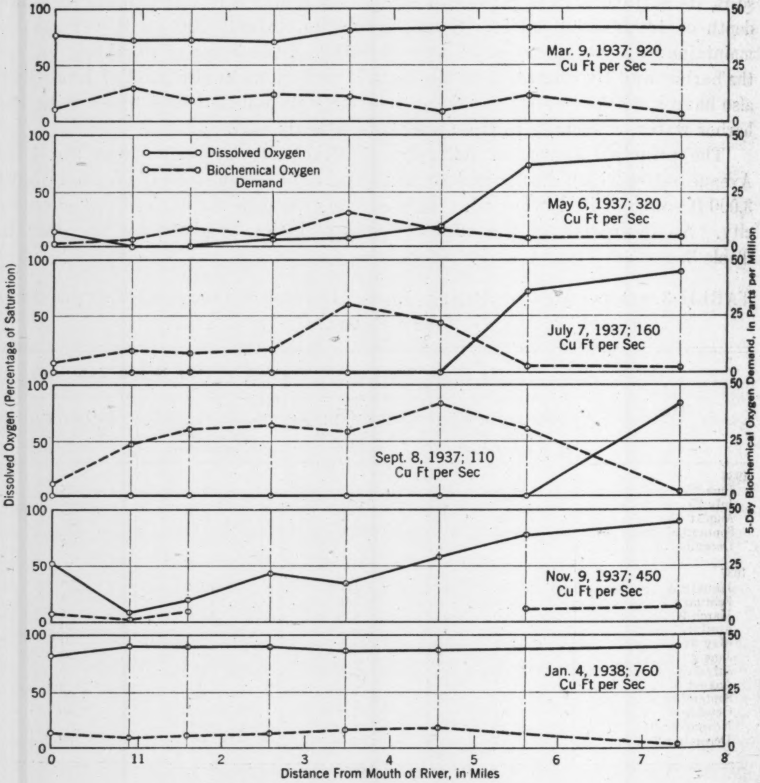

FIG. 2.—CONDITIONS IN BUFFALO RIVER

Fig. 2 shows the dissolved oxygen and the 5-day B.O.D. (bio-chemical oxygen demand) for five typical river surveys during 1937. The river discharges indicated were determined by actual gagings on the dates of the surveys. During the surveys of May, July, and September the dissolved oxygen was practically exhausted.

Scajaquada Creek.—Flowing through the northerly section of the city into Black Rock Harbor, Scajaquada Creek has a drainage area of 24 sq miles. Where it flows through Delaware Park, it has been dammed to form a small lake. Due to the pollution of waters of the creek, sludge deposits in this lake have caused objectionable odor conditions in the past. The section of the creek between the east city limits and Main Street has been enclosed in a large reinforced concrete drain.

ENGINEERING AND LABORATORY WORK

Much field engineering work was required to be done promptly, including surveys for design and for the acquisition of land and rights of way, investigations of the best location for intercepting sewers, the supervision of borings, examination and gaging of existing sewers, and planning and organizing a laboratory. Much useful work was accomplished through the laboratory, in determining sewage quantities and characteristics and the condition of the water in many of the waterways. Studies and reports were made on most of the larger industries. Investigation of the industrial sewages of Buffalo was a major item of the engineering and laboratory work.

During two periods in 1936 (May 14 to 27 and August 5 to 22), and one in 1937 (July 13 to August 28), several of the large sewers were gaged and sampled to determine the dry-weather characteristics of the sewage. The 1937 study was the most extensive and all the following data refer to it. Each sewer was sampled for a period of 8 to 10 days. Chlorine demand was determined on separate samples collected at bi-hourly intervals. Bacterial analyses were made on two samples daily. All other determinations were made on 24-hr composites, built up from samples taken at 15-min intervals and proportioned according to sewage flow. Table 4 gives the results of this work. The sewage

* This sewer includes the flow from all the first four. † The total includes only the last three items—see preceding footnote. ‡ In part.

quantities were determined from measuring the head on weirs built in the sewers.

During 1936, investigations were made as to the effect of storms on the quantity of suspended solids in the sewage, with special attention to the characteristics of the first flushings, which would be taken to the treatment works. In all, some 150 samples were collected, in twelve studies.

The effect of storm runoff on suspended solids is indicated by the study of the Bird Avenue Sewer, results of which are given in Table 5.

Monthly surveys of Niagara River have been made since June, 1936. During the summer months, when the use of a boat was possible, samples were taken at six different cross sections of the river between the site of the treatment plant and the lower end of Grand Island, immediately upstream from the intake of the Niagara Falls water works. About forty stations were sampled at these times. During winter months, samples were obtained only from the two Grand Island bridges, a total of thirteen stations. Analyses were made of each sample to determine the numbers of B. coli and of total bacteria on agar-agar at 37° C. On a few occasions, determinations were also made of dissolved oxygen (D.O.), bio-chemical oxygen demand (B.O.D.), solids, nitrogen, oxygen consumed, alkalinity, and chlorides.

Daily bacterial analyses of the raw water at the Niagara Falls filter plant have been made for the Buffalo Sewer Authority since May, 1936. Two studies were also made to determine the hourly variations in bacterial content of the river water at this point.

Monthly samples from about ten points along the Buffalo River and Cazenovia Creek have been collected and analyzed since April, 1936. The stream discharge and temperature are determined and the following analyses made: Potential of hydrogen, dissolved oxygen, bio-chemical oxygen demand, total solids, suspended solids, oxygen consumed, total nitrogen, chlorides, alkalinity, 37° bacteria, and B. coli. Samples at special locations and for special purposes are collected at various times.

On each of the Buffalo River surveys samples were also collected and analyzed from the following points in the harbors: City Ship Canal at Michigan Avenue, mouth of Buffalo River, Black Rock Harbor at Ferry Street and at Bridge Street.

Occasional studies have been undertaken to determine conditions in the Scajaquada Drain and in Park Lake, with particular attention to sludge deposits and the rate of digestion. Many other more or less extensive investigations have been made covering the chlorine demand of the sewage, hourly variations in sewage characteristics, analyses of materials used in construction, etc.

INDUSTRIES

Buffalo has a relatively large number of industries which produce sewage. Many of these are situated in the southerly part of the city which drains naturally to Buffalo River. Some of the larger plants discharge directly into Buffalo River and do not use the sewers. The chemical industries form an important group, including seven major plants, among which are those of the General Chemical Company and the National Analine and Chemical Company. There are two relatively large coal coking plants, one of which has been closed. There are twenty-four meat packing plants, eleven breweries, fifteen dairies, eight oil handling and refining plants, five rubber reclaiming plants, and five tanneries.

Many of these industrial establishments have been surveyed and the quantities and characteristics of the sewage determined by gagings and analyses. It has been considered that the sewage from some of the industries is not likely to be readily amenable to treatment. It has thus been desirable to undertake a cooperative program with the industries for the removal of pollution from the Buffalo River and from the sewers of the city. This program has proceeded on a satisfactory basis. Properly, it has not been developed until the later steps of construction and the early steps of operation of the treatment plant.

STORM-WATER RELIEF SEWERS

Storm-water relief sewers were planned to serve the Bird Avenue sewer district which has an area of 5,490 acres. The main sewer for this district was inadequate throughout its length, especially the section above Main Street, which has capacities, in its several sections, of only 166 to 665 (gcd), based on estimated 1985 populations. Overflows had been built from this sewer into the Scajaquada Drain, a large sewer which, more or less, is parallel to the Ferry Street sewer to the north. This caused the pollution of Park Lake in Delaware Park. Several lateral sewers in this area were also of insufficient capacity, especially that in Michigan Avenue.

Storm-water relief sewers were planned for a rate of rainfall estimated to occur once in ten years. A runoff coefficient of 0.60 was used for the area within the city limits and of 0.22 for rural areas outside of Buffalo. The size of the necessary relief sewers ranged from 3.5 to 12.0 ft in diameter. The total cost of the storm-water relief sewers was $2,330,000. Plans and specifications for this part of the project were prepared by the City Sewer Department.

INTERCEPTING SEWERS

Intercepting sewers were designed to serve a future population of 1,100,000. The average quantity of sewage of each of the ten major sewer districts (see Fig. 1) was estimated as shown in Table 2. The unit quantities used in computing these sewage flows are as follows:

	Unit rates of average sewage flow
Gallons per capita per 24 hr; domestic	70
Gallons per Acre per 24 Hr:	
Industrial	
North Buffalo	10,000
East Buffalo	12,000
South Buffalo	10,000
Commercial	20,000
Infiltration	
North Buffalo	1,000
East Buffalo	2,000
South Buffalo	4,000

A summary of the estimated average sewage quantities, in million gallons daily, is as follows:

Description	1930	1985
Domestic	40.1	77.0
Industrial	31.6	52.0
Commercial	16.0	24.0
Infiltration	34.4	52.2
Totals	122.1	205.2
Totals, in gallons per capita per day	213	186

For the design of sewers and structures serving only part of the city, the estimated average sewage quantities were increased by factors to allow for a different distribution of the future growth than that estimated. These factors varied with the size of the area served and with the estimated density of population, having a maximum value of 1.5. The factors were applied to the domestic, industrial, and commercial quantities, but not to the infiltration.

For area that will overflow to the Buffalo River the intercepting sewer capacities were based on 3.0 times the estimated 1985 average flow, and for all other areas on 2.5 times the estimated 1985 average flow.

Based on rainfall records and a runoff coefficient of 60%, a computation was made to indicate approximately the number and duration of overflows of combined sewage into the waterways. No very exact computation was attempted, but the approximate results are given in Table 6. A proportion of the total sewage flow varying from about one third of one per cent, in the near future, up to almost one and one third per cent in 1985 will be overflowed during rain storms. Kutter's formula, with $n = 0.013$, was used in determining the capacity of all the intercepting sewers.

Careful studies were made to determine the economical balance between the size and slope of the intercepting sewer and pumping costs. In order to utilize all the head available and at the same time keep the sewer below existing and future utilities, much of the main intercepting sewer was built at a flatter grade than the slope of the hydraulic gradient at maximum flow, so that at times of storm the 11-ft and 9-ft portions of the sewer will operate with the hydraulic gradient as much as 2.5 ft above the crown of the sewer.

TABLE 6.—ESTIMATED FREQUENCY AND DURATION OF OVERFLOW FROM INTERCEPTING SEWERS FOR THE SIX SUMMER MONTHS, MAY TO OCTOBER

A condensed profile of the main intercepting sewer is shown in Fig. 3, and typical sections of the intercepting sewer are shown in Fig. 4. As shown on the profile, the capacity of the sewer varies from 367 to 1,047 gcd, with the higher capacities along the Buffalo River.

For sewers between 3.5 ft and 7 ft in diameter, bidders were allowed to choose any one of four sections: Monolithic concrete, reinforced concrete pipe, brick, and segmental tile. Reinforced concrete pipe (types A and H, Fig. 4) was the choice of bidders in every case, except for monolithic concrete (type B) for earth tunnel in division 0, Fig. 3.

For rock tunnels the horseshoe shape (type C) was used, with a plain concrete lining having a minimum thickness of 8 in. For the larger sewers in open cut, the semi-elliptical section was chosen after extensive investigations of the relative economy of several sections. Drawings of types D, E, and G in

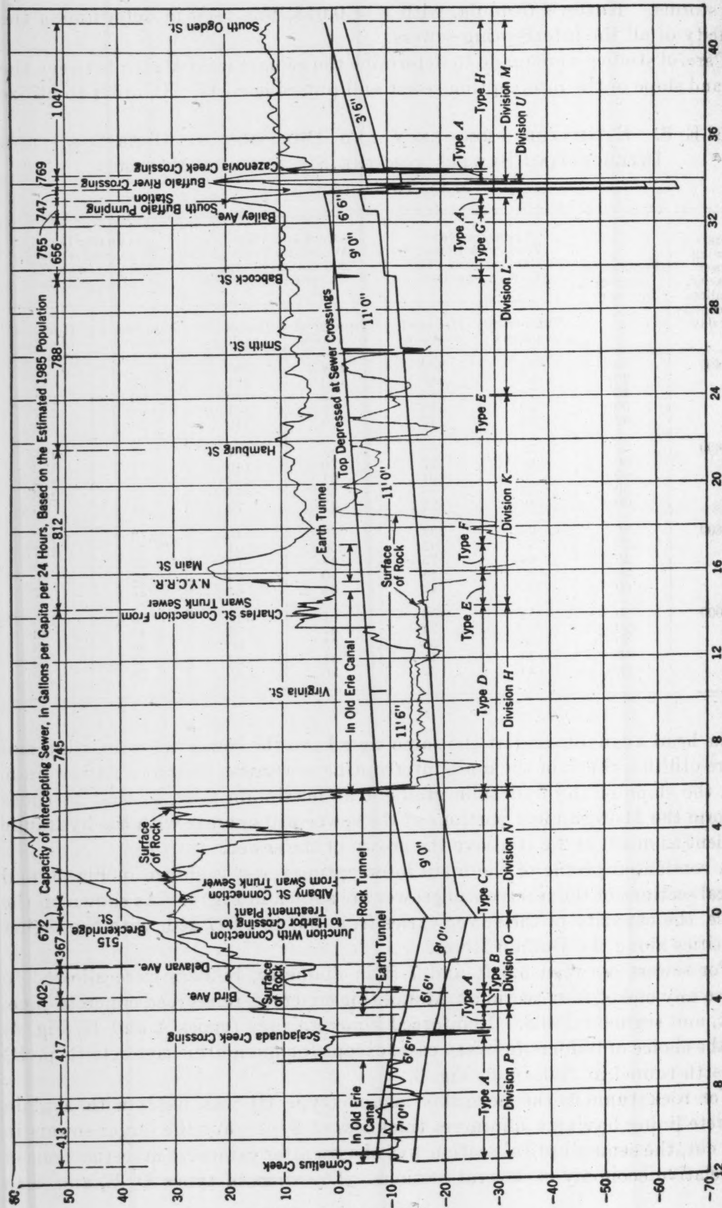

FIG. 8.—GENERAL PROFILE OF INTERCEPTING SEWERS

Fig. 4 show the sizes and dimensions used. "Standard" sections were used for shallow cuts where no extraordinary loading was anticipated. "Heavy" sections were used for deep cuts or where other heavy loads were anticipated, such as from railroad tracks. The entire length of the 11.5-ft, type D section in the abandoned Erie Canal was designed for heavy loads to provide for a proposed relocation of main-line tracks of the New York Central Railroad.

Fig. 4.—Typical Sewer Sections
(All Monolithic Sections Except Type C Contain Steel Reinforcement)

Many special structures were required. Near Bailey Avenue, in the southeastern part of the city, is the South Buffalo pumping station, equipped with four vertical centrifugal pumps having a total rated capacity of 100 mgd. A tunnel crossing under the Buffalo River leads to this pumping station. It comprises two conduits, one 36 in. in diameter and the other, a rectangular section, 4 ft by 6.5 ft. The main crossing under Black Rock Harbor to the

Sewage Treatment Plant comprises two conduits, each 8 ft in diameter. Some 55 intercepting and regulating chambers were built, as well as a large number of special structures including creek and sewer crossings, junction chambers, and several lateral separate sewers.

The estimated final construction cost of the intercepting sewers (exclusive of unsettled claims) may be summarized as follows:

Main intercepting sewer	$5,254,000
Branch sewers	516,000
South Buffalo pumping station	223,000
Harbor crossing	414,000
Total	$6,407,000

The cost of the Main Intercepting Sewer is made up of $4,703,000 for the sewer line proper, including manholes, sheeting left in place, rock excavation, paving, handling utilities, etc.; and $551,000 for special structures, such as intercepting chambers, junction chambers, and river and creek crossings. The sum of $4,703,000 is itemized, as shown in Table 7.

MAIN PUMPING STATION AND SEWAGE TREATMENT PLANT

By special permission of the City of Buffalo, the State of New York, and the United States, the sewage treatment plant is situated on Bird Island, along the west boundary of the city and somewhat north of the east and west center line. The major bases of design are as follows:

Bases of Design

1. Population:

1935	600,000
1939	640,000
1950	750,000

2. Sewage Quantities (All in Million Gallons Daily):

Capacity of intercepting sewer (1985)	563
Capacity of main pumping station	570
1950 basis (population 750,000)	
Average	150
Maximum:	
Clarification and disinfection units	570
Conduits	570
4-hr maximum	570
24-hr maximum	450
2-day maximum	375
3-day maximum	300
Maximum month	200
Minimum (for less than one hour)	80
Near future basis (population 640 000):	
Average	128
Minimum (for less than one hour)	65

3. Sewage Characteristics:

Suspended Solids in Raw Sewage Average (1950):

Parts per million	180
Pounds per capita per 24 hr	0.3

Suspended Solids Removed and To Be Disposed of:

Period	Percentage removal	Pounds per 24 hr
Average	48.0	108,000
Maximum		
24 hr	38.4	448,000
2 days	38.4	351,000
3 days	38.4	278,000
Month	40.0	135,000

(Assume that, as a yearly average, the volatile matter is 70% of the total suspended solids and that at times of maximum flows it is 50%.)

Quantities of Grit:

Period	Cubic yards per million gallons	Cubic yards per 24 hr
Average	0.15	22.5
Maximum		
24 hr	1.0	200.0
Month	0.25	50.0

4. Grit Chambers:

Basis of design, in million gallons daily	570
Number of units or channels	12
Average depth of sewage, in feet	8.0
Length, in feet	65
Width, in feet	10
Velocity, in feet per second:	
Maximum	1.05
Minimum	0.75

5. Screens:
    - Coarse trash racks with bar-spacing of 5.5 in.
    - Bar screens mechanically cleaned with clear spacing of bars at 0.75 in.
6. Sedimentation Tanks:
    - Displacement period at average flow of:

Hours	1.33
Minutes	80.00

7. Raw Sludge Quantities:
    - Percentage of moisture in sludge 96
    - Other quantities:

Period	Gallons of wet sludge per 24 hr	Pounds of dry solids per 24 hr
Average	324,000	108,000
Maximum		
24 hr	1,345,000	448,000
2 days	1,053,000	351,000
3 days	833,000	278,000
Maximum month	405,000	135,000

(Assumed weight of wet sludge, 62.5 lb per cu ft)

Chemicals for conditioning raw sludge, in pounds per 100 lb of dry solids:

	Average	Maximum
Ferric chloride (100%)	2.0	3.0
Lime (CaO)	8.0	12.0

A general plan of the sewage treatment plant is shown in Fig. 5 and a profile showing the high-water and low-water hydraulic grade lines is shown in Fig. 6. The elevations in Fig. 6 are referred to Buffalo City Datum, which is 575.89 ft above mean tide at New York, N. Y. (1903 level adjustment, U. S. Army Engineers). The gradients show that,

(*a*) With river level at − 5.7 and with a sewage flow of 570 mgd, 330 mgd will be discharged through the submerged outlet and 240 mgd through the overflow weir;

(*b*) With river level at − 9.7 and with a sewage flow of 570 mgd, 500 mgd will be discharged through the submerged outlet and 70 mgd through the overflow weir;

(*c*) With river level at − 5.7, sewage flows of as much as 225 mgd will be discharged through the submerged outlet, without overflow; and,

(*d*) With river level at − 9.7, sewage flows of as much as 470 mgd will be discharged through the submerged outlet, without overflow.

The treatment plant occupies a somewhat triangular shaped site, having an area of 23.0 acres. At the southerly end is the main pumping station which lifts the sewage about 23 ft at average sewage flow. The sewage then flows by gravity through a screen and grit chamber, venturi meters, aerated channels, four sedimentation tanks, and a submerged outfall to the Niagara River.

FIG. 6.—HYDRAULIC PROFILE, SEWAGE TREATMENT PLANT

The pumping building contains six vertical, close-coupled, centrifugal pumps, each with a rated capacity of 100 mgd and a low-head capacity of 120 mgd. The total capacity of the pumping station is thus somewhat more than that of the intercepting sewer system. Two of the pumps are fitted with two-speed motors to assist in uniform regulation of flow into the sedimentation tanks.

There are twelve grit chambers. Each pair operates as a unit with one bar screen and pump, and there are no cross connections between these units. Screenings are discharged into grinders and returned thence to the sewage. The grit chambers proper are 60 ft long and 10 ft wide; and they have an average liquid depth of 10 ft.

After leaving the grit chambers, sewage flows through two conduits under the main building, each conduit having a venturi tube. Following the venturi tubes, the two conduits are equipped with plates and piping for aerating the sewage. This section of the conduits is 285 ft long and traverses a part of the site left open, for the present, to provide for future structures. Chlorine is added to the sewage at the far end of these aerated conduits near the sedimentation tanks. The chlorination equipment is housed in the main building.

The sewage then flows through a by-pass and control chamber to four circular sedimentation tanks which provide a displacement period of 80 min at rated capacity. Each of these sedimentation tanks is 160 ft in diameter, and the side-water depth is 14.5 ft. Effluent from the sedimentation tanks flows into the Niagara River about 200 ft from shore, at a depth of about 40 ft.

The suspended solids are pumped from the sedimentation tanks to four sludge storage tanks, having a total capacity of 750,000 cu ft, or 1.0 cu ft per capita. Each tank is 90 ft in diameter, with side and center depths of 27 ft and 38 ft, respectively. Each of the tanks is equipped with a floating cover.

In the center of the space occupied by the sludge storage tanks is a building that houses sludge pumping and control equipment with provision for the delivery of sludge at given rates into one or all of the four tanks, the transfer of sludge from one tank to another, and to the sludge-disposal building (see Fig. 5).

The sludge disposal building contains three de-watering filters of the vacuum type, three flash-type sludge incinerators, and the boiler plant for heating the sludge storage tanks and all buildings. Each drum filter is 11.5 ft in diameter and 14 ft long, with a filtering area of 500 sq ft. It is estimated that these filters will de-water the sludge to a moisture content of 70%, at the average rate of 5.0 lb of dry solids per sq ft per hr when conditioned with about 2.0% ferric chloride and 8.0% lime (expressed as CaO).

Sludge cake from the filters is discharged on to a belt conveyer extending the length of the building which, in turn, discharges to a cross conveyer where the sludge is weighed and elevated to another longitudinal conveyer which delivers it to the sludge incinerator units.

Sludge cake, mixed with previously dried sludge, is delivered to flash dryers in the sludge incinerators; thence it is blown into the furnaces for combustion. Any deficiency in heat units is made up by burning oil or gas. The sludge incinerators include ash-removal equipment, fly ash cyclones, and other appurtenances. Each of the three incinerators has a rated capacity of 100 tons of sludge cake (containing 70% moisture) per 24 hr. Two of the incineration units will probably be sufficient to dispose of the average quantity of sludge.

The various features of the sewage treatment plant are connected by a service tunnel along one side of which the main ventilating duct is constructed. The several parts and buildings of the plant where sewage is exposed are provided with large ventilating fans which withdraw air and discharge it into this main ventilating duct. The chimney of the treatment plant, rising 175 ft above the ground, is actually two concentric ducts. The inner of these is for the hot gases from the sludge incinerators and the boiler plant, and the outer, or annular one, is for ventilation and receives the air blown through the main ventilating duct.

The main building houses the office and laboratory, garage, machine shop, blowers for the aerated conduits, chlorine equipment, and the plant water supply, including pumps and elevated tank. A flow diagram of the sewage treatment plant is shown in Fig. 7(*a*), and of a sludge incineration unit in Fig. 7(*b*).

The approximate total cost of the main sewage pumping station and sewage treatment plant was $4,378,891, distributed as follows:

Contract division	Total cost
Preparation of site	$ 166,867
Pumping station and grit chamber	914,429
Sedimentation tanks	772,921
Pumping equipment	324,000
Electrical work	115,537
Sluice gates	49,375
Sludge de-watering equipment	74,965
Incineration equipment	257,500
Sludge disposal building	298,670
Sludge storage tanks	414,807
Brick stack	28,881
Electrical work	35,978
Boiler plant equipment	69,314
Outfall structure	102,897
Main building, service tunnels, sewage conduits, and meters	600,546
Trucks	13,266
Yard water piping equipment	22,327
Roads and walks	54,941
Wall around sedimentation tanks	16,670
Landscaping	20,000
Miscellaneous informal bids	25,000
Total	$4,378,891

The part of this total sum required for sewage treatment is about $3,500,000, which is equivalent to $4.67 per capita or $23,300 per mgd of design capacity.

FIG. 7.—FLOW DIAGRAMS

A summary of the estimated final costs for the major divisions of the sewage treatment plant construction is shown in Table 8. For the most part, bids were received on a unit price basis. Table 8 shows the high and the low bids of the successful bidders and a weighted average for each kind of construction for which unit price bids were received.

TABLE 8.—SUMMARY OF BIDS ON UNIT PRICE ITEMS, BY SUCCESSFUL BIDDERS; SEWAGE TREATMENT PLANT

Item No.	Description	High	Low	Weighted average
1	Earth excavation, in cubic yards	$ 4.00	$ 1.00	$ 2.90

REVENUES AND EXPENSES

Under the act creating it, the Buffalo Sewer Authority has taken over the maintenance and operation of all of the sewers of the city. Thus, estimates of annual operating costs include items for the maintenance of lateral sewers, for sewer cleaning and repairs, and for progressive rehabilitation. In round numbers, the annual budget is summarized as follows:

Item	Annual sum
Administration and expense of main office	$ 80,000
Collecting sewers	223,000
Outlying pumping stations	59,000
Sewage treatment plant	397,000
Construction work, insurance, and miscellaneous	141,000
Debt service	600,000
Total	$1,500,000

The Authority has adopted a two-part rate schedule for raising the annual revenue. This rate schedule provides that 55% of the total sum (or $825,000) shall be derived from a charge based on water consumption; and that the remainder (or $675,000 per yr) shall be derived from a charge to be paid by all taxable property in proportion to the assessed valuation. The portion of the rate applicable to water use is 40% of the water rates, and the portion applicable to assessed valuation is about $0.73 per $1,000.

ACKNOWLEDGMENT

Many individuals have contributed to the progress and outcome of the Buffalo Sewage Disposal Project. Probably the only satisfactory acknowledgment would include a roster of all of the engineers and administrative officers connected with the work. Among those who have devoted considerable effort are the following:

Members of the Buffalo Sewer Authority.—Daniel H. McCarriagher, Chairman, Henry W. Keitzel, Kevin Killeen, William M. Coon, Myron G. Lehman, George W. Lennon, and Christy J. Buscaglia.

Members of the Firm of Greeley and Hansen.—C. R. Velzy (later superintendent of operation for the Sewer Authority), and J. R. Rumsey, Members, Am. Soc. C. E.; F. C. Sellnow and L. G. Williams, Associate Members, Am. Soc. C. E.; and P. E. Langdon, S. M. Clarke, J. K. Geisey, and T. M. Niles. The firm of Greeley and Hansen served as designing and supervising engineers.

The City of Buffalo, N. Y.—Carl Howell, engineer in charge of sewers for the City, Edward P. Lupfer, M. Am. Soc. C. E., directing engineer for the Buffalo Sewer Authority, and G. E. Symons, chief chemist.

U. S. Public Works Administration.—Harold Epstein, project engineer (later general manager in charge of operation and maintenance of the entire sewerage system of the Buffalo Sewer Authority), and E. L. Peterson, supervising engineer.

DISCUSSION

C. A. Holmquist,[2] Esq. (by letter).—The pollution of Niagara River by sewage and wastes from Buffalo and other municipalities has been a matter of grave and growing concern to the Sanitary Engineering Division of the State Department of Health ever since its organization in 1906. For many years, the polluted Niagara River has been the source of water supply for the cities of Lockport, Tonawanda, North Tonawanda, and Niagara Falls, and the villages of Lewiston, N. Y., Youngstown, and Fort Niagara, having a combined population of approximately 140,000. Years ago, and before water-filtration plants had come into common use, these communities suffered repeated outbreaks and an extremely high incidence of typhoid fever. Niagara Falls, for example, prior to construction of its water-filtration plant in 1912, had the highest typhoid-fever death rate of any city in the state, reaching a maximum of 185 per hundred thousand in 1905 and averaging 131.2 for the 12-yr period ending in 1912.

The installation of water-filtration and chlorination plants at Niagara Falls in 1912 produced the immediate effect of lowering the typhoid death rate greatly. There has not been a single typhoid outbreak in the city traceable to the public water supply since 1913, and there have been only two deaths from typhoid since 1925 from any cause. This naturally speaks well for the efficient operation of the city's water-filtration plants. The improvements made to the water supplies of other communities along the Niagara River produced similar effects on the typhoid-fever death rates.

A number of investigations of the pollution of the Niagara River by the Department of Health have shown that the sewage and wastes discharged into the river from Buffalo have a tendency to become stratified laterally and to "hug" the easterly shore of the easterly channel of the river. This condition naturally has afforded considerable protection to the water intakes which are located near the westerly shore. This so-called "natural barrier" and the greatly reduced typhoid-fever death rates, as a result of water-supply improvements, have been advanced as arguments against the construction of sewage treatment facilities by the city of Buffalo.

Limitations in the Public Health Law made it difficult to act to require installation of sewage treatment facilities by Buffalo in the face of reductions of the typhoid-fever death rate which had occurred. Furthermore, industrial wastes were a large and important factor in the pollution of the Niagara River, and the Public Health Law exempts industrial wastes from application of the law unless they are mixed with sewage. Over the course of many years the State Department of Health had tried repeatedly, but without success, to have the laws amended to give it more authority to control pollution and to simplify the somewhat cumbersome procedures established for its enforcement. These were some of the difficulties which the Department of Health had always encountered in its repeated efforts to have Buffalo provide adequate treatment facilities.

---

[2] Director, Div. of Sanitation, New York State Dept. of Health, Albany, N. Y.

The several investigations made by the Department of Health over a period of fifteen years showed clearly that pollution of the Niagara River was increasing, and that at times the lateral stratification of pollution in the river was not so effective a barrier as it was thought to be at one time. The Department of Health always recognized, notwithstanding the reduction in typhoid fever which had been achieved, that the situation was one which could easily lead to an explosive outbreak under the failure of water-treatment processes. It was for this reason that every effort was made to secure action by the City of Buffalo.

The entire matter of abatement of pollution along the Niagara frontier "came to a head" in 1931 when the governor was convinced by the state commissioner of health that the situation held great promise for a calamity in the near future. Accordingly, the governor called into conference representatives of all the Niagara frontier municipalities and requested them to show cause why orders should not be issued requiring the abatement of the dangerous pollution. Buffalo, represented by its mayor, commissioner of public works, and corporation counsel, admitted its responsibility for the pollution but claimed that it could not finance the cost of treatment works without greatly exceeding the limit of its borrowing power. The other municipalities along the river agreed in effect to install treatment facilities as soon as Buffalo proceeded with a solution of its problem (which was, of course, the major problem).

No definite action resulted immediately from this conference, although it served the good purpose of impressing upon Buffalo and these other communities that pollution of the river could not be tolerated much longer. The Depression occurred and it was impossible, for a time, to induce municipalities to make appropriations for public improvements.

Then in March, 1933, came a "wave of pollution" which swept down Niagara River and through Lake Ontario, affecting practically every water plant with intakes extending into either the Niagara River or Lake Ontario, and causing an outbreak of about 10,000 cases of gastro-enteritis in the City of Niagara Falls. This experience and the threats to the lives and health of thousands of persons served to strengthen, greatly, the Department of Health's case against the City of Buffalo.

Funds were becoming available from the U. S. Public Works Administration (PWA) about that time, and persistent efforts were made to induce the city to take advantage of the opportunity of federal aid for construction of the necessary facilities. Still the city did not move toward solution of this problem except through the construction of some storm-water relief sewers.

Early in 1935 another wave of pollution swept down Niagara River, which again threatened the safety of many public water supplies. The state commissioner of health decided that positive action against the city must be taken, and accordingly he instituted proceedings against Buffalo early in 1935, which resulted in the prompt issuance of an order, approved both by the governor and the attorney general, and which contained the following conditions:

(1) That a consulting engineer be engaged by May 1, 1935;

(2) That the purchase of the land for the sewage treatment works be authorized by June 15, 1935;

(3) That detailed plans and specifications for the Bird Avenue storm drain be submitted to the State Department of Health for approval by September 1, 1935;

(4) That comprehensive plans for the interception and treatment of the entire city's sanitary sewage, and necessary storm-water relief sewers, be submitted to the State Department of Health for approval by October 1, 1935;

(5) That detailed plans and specifications for sewage treatment works and a sanitary sewer system be submitted to the State Department of Health for approval by April 1, 1936, and that work be started by July 1, 1936, and the treatment works completed and placed in operation by October 1, 1937; and

(6) That by October 1, 1935, the City of Buffalo submit to the State Department of Health, for approval, a satisfactory program for the construction of the remaining interceptors, pumping stations, force mains, and storm-water relief drains to provide for the interception and treatment of the sanitary sewage of the city, together with the percentage of storm-water flow to be treated by the sewage treatment works.

However, its existing indebtedness made it impossible for Buffalo to finance the works by ordinary methods. Accordingly, the city had legislation enacted providing for the creation of a sewer authority with power to take over the sewer system, issue bonds, and establish sewer rentals for the financing of the cost of the city's share of the project and pay for the operation of the works. The city received a 45% grant from the PWA, amounting to approximately $7,000,000.

Almost simultaneously the City of Niagara Falls undertook the construction of intercepting sewers and sewage treatment works, which were completed in 1939. It was necessary, however, to take steps to order the cities of Tonawanda and North Tonawanda to install similar works. With the installation of treatment works for these two remaining cities, the chapter of pollution of the Niagara River will be closed, and one of the most serious cases of pollution in New York State will have been abated.

ARTHUR J. BULGER,[3] ESQ. (by letter).—The author's purpose to record some of the engineering data accumulated during the design and construction of the project has been ably effected. The information is a valuable addition to the fund of such data.

A statement of the factors leading to the selection of the percentage of annual costs to be raised by a charge based on water consumption, and its relation to that portion of the annual costs to be derived from an ad valorem tax, would have been both interesting and timely. Payment of annual costs for sewerage works by a rental charge for services is not new, but its use has been limited until the past few years to a relatively small number of plants.

In principle the two-part rate schedule adopted by the Buffalo Sewer Authority appears to offer a more equitable distribution of cost to benefits than an all-revenue schedule or payment entirely by ad valorem tax. The issuance of part revenue bonds and part general obligation bonds as security for construction funds has resulted, in some cases, in a similar allocation of costs. However, in this procedure, operating expenses are usually paid entirely from revenues.

---

[3] Director, Eng. Div., Federal Works Agency, Public Works Administration, Washington, D. C.

Digressing somewhat from the stated purpose of the author, the project at Buffalo is of peculiar interest because of its international aspect. Although a problem of the local community, the completion of the project should be gratifying to the nation since it has removed a condition displeasing not only to the citizens of Buffalo but also to the nation's good neighbors in the north as well. Furthermore, this project is an example of the influence of the Public Works Administration in materially accelerating the job of removing undue pollution from surface waters.

The Buffalo Authority and its engineers are to be congratulated on a job well conceived and executed.

C. R. Velzy,[4] M. Am. Soc. C. E. (by letter).—Some of the operating results of the sewage treatment works at Buffalo are reported herein, with comments on the accomplishments thus far attained by the sewage disposal project.

The first sewage, amounting to about 20 mgd, was turned into the interceptor on June 18, 1938. Following that date, other connections from various parts of the Buffalo sewer system were opened into the interceptor until, by July 1, 1938, the entire flow of the city was being received, pumped, and treated at the treatment works. Although final construction was not completed for more than a year thereafter, the structures essential to the starting of treatment were ready for use on this date, and treatment has continued without interruption since that time.

Records of operating results have been kept from the beginning, some of the more pertinent being included in Table 9. Where available, corresponding data from the bases of design are shown. It should be borne in mind that, due to construction and testing activities during the first eighteen months of operation, the results do not, in all cases, represent normal conditions. Partial interruption of settling tank operation and return of heavy supernatant to the settling tanks during interruptions in sludge disposal processes are illustrative of interferences with normal operation.

Table 9(*a*) contains data on population and flows. It is worthy of note that the population has not increased as rapidly as was expected in 1935. The average flow has been very close to the rate estimated, but, as might be expected, maximum rates have varied somewhat from the estimate. The maximum rate of 560 mgd occurred on September 14, 1938, and lasted about one hour.

The data on grit and suspended solids shown in Table 9(*b*) indicate raw sewage characteristics in accordance with the bases of design. The removal of suspended solids was handicapped by necessary irregularity in plant operation. Results obtained in some of the more normal months indicate that the removal will range from 43% to 50%, with an effluent containing somewhat less than 100 ppm of suspended solids.

---

[4] Works Supt., Buffalo Sewer Authority, Buffalo, N. Y.

Although the chlorine demand has been consistent, there are wide variations in short-period demand due to return of heavy supernatant and also apparently to the occasional discharge of industrial wastes of high demand. By hourly sampling and testing, the application of chlorine is made to follow the requirements closely, and a satisfactory kill of coliform bacteria is maintained at all times as shown in Table 9(*c*).

NIAGARA RIVER

FIG. 8.—HYDRAULIC PROFILE; MARCH, 1938; SEWAGE TREATMENT PLANT

The raw sludge has been characterized by low moisture content and a low percentage of volatile matter. The volatile content was affected by return of heavy supernatant which was low in volatile matter. Gas production has been good, and in October, 1939, the maximum rate of gas production was reached, amounting to 0.93 cu ft per capita per day. These data are shown in Table 9(*d*).

Some data on sludge disposal are given in Table 9(*e*). The filtering of sludge has been particularly successful in the low moisture obtained in the sludge cake and in the relatively high filtering rate. The rate for the last six months of 1939 was 8.3 lb of dry solids per sq ft per hr as compared to a guarantee of 5 lb. The maximum rate of 13.4 lb per sq ft per hr was reached in August, 1939. It is expected that refinement in the control of the application of chemicals will result in the use of less chemicals than have thus far been found necessary.

During the first year, the incinerators were under tests most of the time and rates of burning were not recorded. However, from July, 1939, to January, 1940, the rates of burning of dry solids have averaged 2,610 lb per furnace hour as compared to a guarantee of 2,500 lb per furnace hour.

Fig. 6 shows a profile through the treatment works and a high-water and low-water hydraulic grade line. Although no observations have been made to determine the rate of sewage flow at which spilling over the overflow weir in the outfall takes place, observations of the hydraulic grade line through the plant for a high and a low rate of flow are shown in Fig. 8.

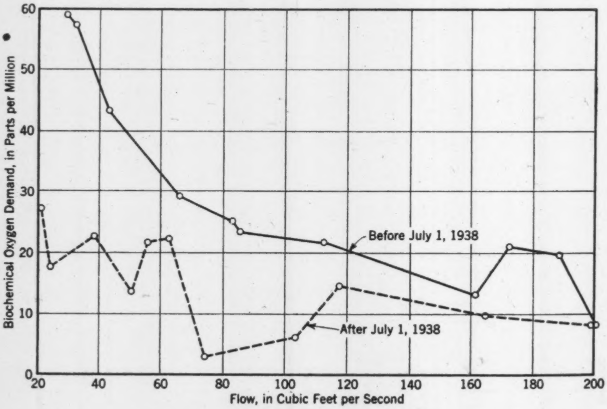

FIG. 9.—CONDITIONS IN BUFFALO RIVER

Under the heading "General Statement" Mr. Greeley presents the three objectives of the sewage disposal project. Monthly observations of the bordering waterways have been made by the laboratory staff under the direction of George E. Symons who has charge of the laboratory work of the Buffalo Sewer Authority.

Results of observations on the conditions in the Buffalo River before the treatment works went into operation and after they were in operation are shown in Fig. 9. These data are from averages of analyses of samples taken at four sampling stations in the middle stretches of the river somewhat above the outlet. The data and results herein are based on flows as great as 200 cu ft per sec. It will be noted that the data taken after July 1, 1938, even for a lower average flow, show a definite decrease in 5-day B.O.D. Observations showed a reduction in coliform bacteria of 43%. A definite increase in dissolved oxygen is evident in that, before July, 1938, it was found only in flows greater than about 160 cu ft per sec, whereas, after that date, it was found in flows as low as 100 cu ft per sec.

Some parts of Buffalo Harbor are directly affected by the Buffalo River. These parts enjoyed an improvement corresponding to the improvement in the river. Before July, 1938, Black Rock Harbor became quite septic in the summer months, with a high bio-chemical oxygen demand and coliform content. This was due to the discharge of one of the main sewer outlets into the harbor. After the treatment works went into operation, the waters of this harbor became fresh, with a dissolved oxygen content of about 6 to 7 ppm in the summer months. The reduction in a 5-day B.O.D. is shown in Table 10.

TABLE 10.—COMPARISON OF BIO-CHEMICAL OXYGEN DEMAND, IN PARTS PER MILLION

Date (1938)	January	February	March	April	May	June	July	August	September	October	November	December
Before July 1	28	15	3	30	35	29	17.	11	24	28	..	33
After July 1	3	..	..	5	0	4	0.2	1	2	2	2	2

Monthly samples have been taken and analyses made on the Niagara River, and it has been observed that the quantities of coliform bacteria have been reduced about 97% from the average for some two years previous to the beginning of operation. Water works below Buffalo report longer filter runs and reduction in the quantity of wash water and chlorine required. Reduction in sludge deposits and the return of game fish immediately below Buffalo are reported.

By intercepting Scajaquada Creek the Main Intercepting Sewer has removed a flow of sewage from Park Lake, an attractive body of water in Delaware Park, and has thus eliminated a serious odor nuisance which previously prevailed during the summer months.

With the completion of construction and testing, normal operating results as well as refinements and economies are anticipated. Further work on industrial waste disposal, with the continuation of excellent cooperation from the industries involved, will result in further improvement in the condition of adjacent waterways.

The operating results at the treatment works and the effects upon the waterways of Buffalo obtained during these first months of operation indicate the soundness of the bases of design and show accomplishment of the objectives which are described in Mr. Greeley's paper.

THOMAS M. NILES,[5] M. AM. SOC. C. E. (by letter).—The tunnel crossing under the Buffalo River and the main crossing under Black Rock Harbor to the sewage treatment plant are described briefly in this paper. Two additional crossings, not mentioned by name in Mr. Greeley's paper, were built under Cazenovia Creek and Scajaquada Creek. Structures of this kind are frequently required in connection with sewer work.

Black Rock Harbor is a relatively short navigable canal along the east bank of the Niagara River which carries traffic past the rapids at the head of the river. At the point of crossing it has a total width of about 400 ft, a channel width of about 250 ft, and a channel depth of about 20 ft. To allow for a future navigable depth of 27 ft, the War Department requested a clear depth of not less than 32 ft over the crossing structure, measured from low water datum. This was the only one of the four stream crossings at which active navigation had to be maintained during construction.

Although the Buffalo River is considered navigable as far as Bailey Avenue, the point of the sewer crossing, it is not now (1940) used this far up. The stream at this point is some 200 ft wide and 5 to 7 ft deep below low water. To provide for future navigation, the required depth over the crossing structure was 30 ft. Actually, this crossing was constructed in rock tunnel at a greater depth.

Cazenovia Creek and Scajaquada Creek are about 120 ft wide and 50 ft wide, respectively, and are both about 10 ft deep. The clear depth necessary was 14 ft for the former and 16 ft for the latter. Although both may be considered navigable, no development for deep draft vessels is contemplated.

The crossings were designed to provide velocities sufficient to avoid deposition of organic solids at minimum flows and sufficient to scour sand and grit at maximum flows, with reasonably low loss of head. Other controlling factors were simplicity of construction, simplicity of operation, ease of inspection and maintenance, and the provision of facilities for cleaning if found necessary.

Two-pipe conduits were used for all of the crossings. Those for Cazenovia Creek and Scajaquada Creek are circular reinforced concrete pipes encased in concrete. In the Buffalo River Crossing, the smaller pipe is circular and the larger a modified rectangular section with the longer dimension vertical with a semicircular crown. The harbor crossing consisted of two pipes of equal diameter. For all except the harbor crossing, where flow is controlled manually by sluice gates, dry weather flow is confined to the smaller pipes by means of weirs.

Table 11 presents data on sewage quantities, pipe sizes, velocities, and estimated loss of head for the four crossings. In the two creek crossings the pipes are of the same cross sections throughout their lengths and the inlet and outlet portions are sloped down from inlet chambers and up to outlet chambers which meet the inverts of the connecting sewers. The river and harbor crossings have vertical inlet and outlet shafts, and in the case of the river crossing the uptake pipes in the outlet shaft are reduced in size to 30-in. diameter and 48-in. by 54-in. rectangular to provide slightly higher velocities than in the horizontal part of the crossing.

---

[5] Engr., Greeley & Hansen, Chicago, Ill.

Inlet and outlet chambers for the creek and river crossings are provided with removable slabs to permit introduction of dewatering pumps and other equipment which may be useful in connection with inspection and cleaning. During dry-weather flow, the larger pipes of the creek crossings may be pumped out and inspected without disturbing the flow in the smaller pipes. Inspection of the smaller pipes involves construction of temporary dams to divert the flow through the larger pipes. Sluice gates are provided at both the inlet and outlet ends of the river and harbor crossings to permit diversion of flow to either pipe while the other is being inspected.

TABLE 11.—DESIGN DATA FOR STREAM CROSSINGS, BUFFALO SEWAGE DISPOSAL PROJECT

Crossing	1940 Sewage Quantities, in Million Gallons Daily			Pipe Diameters, in Inches		1940 Velocities, in Feet per Second					Estimated loss of head, in feet, at maximum flow
						Smaller Pipe				Maximum velocities, larger pipe	
	Minimum	Average	Maximum	Smaller	Larger	Minimum	Average	Maximum	At maximum flow		
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)

Scajaquada Creek.....	9	19	97	36	60	2.0	4.2	7.7†	5.9	5.6	1.0
Buffalo River........	7	14	87	36	*	1.5	3.0	5.5†	4.2	4.3	2.3
Black Rock Harbor...	66	132	566	96	96	1.0	2.0	8.7	8.7	8.7	5.5

* Special shape (48 in. by 77 in.), area = 24 sq ft.

† Maximum velocities occur in the smaller pipes just before the larger pipes come into service. Advantage is taken of an available head somewhat higher than the head available at maximum total flow.

The outlet structure of the Buffalo River crossing includes a separate access shaft between the two riser pipes sufficiently large to accommodate a dewatering pump and other equipment that may be needed. Manholes at the bottom of this shaft permit access into the horizontal crossing pipes, and gate valves are provided for draining the pipes into the shaft.

The harbor crossing riser pipes are within the inlet chamber of the main pumping station at the treatment plant. They are vertical tubes, 8 ft in diameter, opening into surge chambers with an overflow connection to the river. These tubes extend 2 ft below the inverts of the horizontal crossing pipes to form pockets for the collection of large stones which may not be carried upward, and from which material may be periodically cleaned by means of a clamshell bucket. A portable dewatering pump is provided to facilitate inspection and cleaning.

Construction of the two creek crossings was by open cut with cofferdams in two sections, confining the stream flow to the inactive half of the work. Aside from occasional flooding from high water, no unusual difficulties were experienced.

Alternate methods of construction, open cut or rock tunnel, were available to bidders on the Buffalo River crossing. The low bid was for rock tunnel and the contractor exercised his option to construct the tunnel at a lower elevation than shown on the plans in order to obtain more favorable tunneling conditions. Even so, it was found necessary to install timbering for roof support. Occasional grouting of seams successfully controlled the flow of water into the work.

Borings had shown the material at the site of the Black Rock Harbor crossing to be unsuitable for tunneling. Accordingly, the construction method available was open cut, either by cofferdams or by subaqueous methods. Although proposals were received on both methods, the low bidder's choice of the subaqueous method involved less difficulty in maintaining navigation during the progress of the work. Considerable additional dredging would have been required to provide sufficient widths and depths of channels at either side had cofferdams been used throughout.

Approximate average construction costs for the four stream crossings, including inlet and outlet structures, were as follows:

Crossing	Total	Per foot of length
Scajaquada Creek	$ 15,000	$150
Cazenovia Creek	27,000	150
Buffalo River	75,000	300
Black Rock Harbor	425,000	800

The crossings were placed in operation in June, 1938, and have given satisfactory service. No operating difficulties have been encountered and there has been no need for cleaning.

The foregoing discussion of one feature of the work on the Buffalo project is perhaps in more detail than the relative importance of this feature should warrant. Nevertheless, it has seemed that the material presented may be of value in acquainting the reader with some of the detailed considerations which entered into the design. The paper itself is an admirably complete and concise review of the essential features of the project and contains sufficient detailed information to present a clear understanding of the problem at Buffalo and the manner in which it was solved.

SAMUEL A. GREELEY,[6] M. Am. Soc. C. E. (by letter).—The writer was very much interested in the discussions submitted. Those by Messrs. Velzy and Niles add much of interest to the record of the engineering data of the Buffalo Sewage Disposal Project.

Mr. Bulger comments on the two-part rate schedule adopted by the Buffalo Sewer Authority to provide the necessary annual revenue. The collection of revenues under this two-part rate schedule was done for two complete fiscal years on June 30, 1940, and the results were gratifying. The following is quoted from a publication of the Manufacturers and Traders Trust Company of Buffalo, in 1940, with reference to the sale by public bidding of $500,000 of bonds of the Authority:

> "Receipts for the fiscal year [1938–1939] have been uniformly good, being 94+% of that part of the Sewer Rent based upon assessed valuation of property and 93+% for that part of Sewer Rent based upon water consumption."

---

[6] Greeley & Hansen, Chicago, Ill.

The purpose of the two-part rate schedule is to provide equity in the contribution of persons to the necessary annual revenue. The two-part rate has been commented on in a publication of general interest by the Buffalo Sewer Authority (dated 1938) as follows:

> "The Buffalo Sewer Authority in trying to fix upon the most equitable method of raising the money to pay for building and operating the new sewer system, decided that it would be unfair to put the entire burden on real estate owners; also, that it would be unfair to put the entire burden on water users. After a very thorough and painstaking study of all of the facts, it was decided to divide the expense.
>
> "Fifty-five percent of the annual revenue, or $825,000, is collected on the basis of water use, and forty-five percent, or $675,000, is collected as a charge for sewage disposal service computed on the basis of assessed valuation."

It is the writer's opinion that the two-part rate permits equitable distribution of the cost of sewerage and sewage disposal service, particularly in cities having combined sewers, such as Buffalo.

FUNCTIONAL DESIGN OF FLOOD CONTROL RESERVOIRS

By C. J. Posey,[1] Jun. Am. Soc. C. E., and Fu-Te I,[2] Esq.

With Discussion by Messrs. Edward Soucek, J. C. Stevens, Edward J. Bednarski, Roland A. Kampmeier, Edgar E. Foster, Sherman M. Woodward, M. Kindinger, P. Wilhelm Werner, Waldo E. Smith, J. O. Jones, W. C. Hammatt, and C. J. Posey and Fu-Te I.

Synopsis

The functional design of a flood control reservoir has as its objective the determination of the relation between the storage space that must be provided and the corresponding reduction of the flood peak. The method of incorporating this relation into the study of the economic balance of a flood control system has been explained in detail by Sherman M. Woodward,[3] M. Am. Soc. C. E. Mr. Woodward's "five-sixths rule," which heretofore has provided the only direct method for the functional design computations, is limited in its application to reservoirs of such proportions that the maximum outflow is small compared with the average inflow during the flood, and to reservoirs with orifice-type outlets and a certain type of depth-capacity relationship. In this paper the writers have generalized Mr. Woodward's method and have extended it to apply to reservoirs with either orifice- or weir-type outlets, in valleys of a wide range of morphological configuration. Although the relationships derived can be used in the design of multiple-purpose reservoirs, the present discussion is restricted to reservoirs for flood control only.

Introduction

A necessary preliminary step is the estimation of the maximum flood run-off that may occur at the given site. This is usually based upon a statistical study of meteorological and hydrological data, and includes a determination of the shape of the flood hydrograph, as well as its volume. Methods of making

these studies have been the subject of extended discussion in recent years,[4] and further treatment is not necessary in this paper. Suffice to it say that the flood hydrograph used for the design is made somewhat greater than the maximum probable flood to provide a margin of safety. No matter how carefully this work is done, the design flood will have the kind of uncertainty that is attached to any prediction of future events. This sets a limit of accuracy beyond which it is useless to carry subsequent computations.

In order to determine the storage necessary to accomplish a desired reduction of peak flood flow, it is necessary to route the design flood through the reservoir—that is, to compute the moderating effect of the reservoir storage upon the flood hydrograph.

In general, flood-routing methods are of two types:

(1) Step methods, in which the flood inflow hydrograph is divided into steps or time intervals of such short duration that during each one the inflow and outflow rates may be assumed to be constant. The actual depth-capacity data for the reservoir site are used and the discharge-depth relation must be known. An irregular inflow hydrograph may be approximated, as closely as desired, by using a large number of steps.

(2) Integration methods, in which the given flood hydrograph is replaced by an equivalent flood of uniform intensity. The depth-capacity data are represented by an empirical formula. It is necessary to know only the exponent and approximate zero-depth of the discharge-depth relation.

The first step methods to be used required a trial-and-error solution of each step. Later, graphical methods were developed which eliminated this cut-and-try process.[5] Results of the step computations include the outflow and stage at the end of each step, so that step methods are well adapted for operation studies. In application to functional design, however, step methods are indirect. It is necessary first to assume the size of the outlet. The corresponding maximum storage and maximum outflow are determined by means of routing computations. Another size of outlet is then assumed, and the process is repeated until the desired part of the curve representing the relation between storage and percentage reduction in flood peak has been obtained. On the other hand, integration methods give the storage required for a given maximum outflow directly, with considerable saving of time and labor.[6]

Depth-Capacity Exponent.—The relation between depths and capacities in the reservoir may be represented by an empirical expression of the form

$$s = C\,h^m \qquad (1)$$

in which: s is the storage capacity of the reservoir at a depth h; h is the depth of water above outlet; C is a constant; and m is the "depth-capacity" exponent. For the determination of m, logarithmic plotting is used. The depths above outlet location (zero depth of the orifice type of outlet, or the crest of a weir type of outlet) are plotted as ordinates and the corresponding capacities as abscissas. A straight line best fitting the plotted points is drawn. The exponent m is the reciprocal of the slope of the line, the slope being measured directly with a scale having uniformly spaced divisions, disregarding the logarithmic scale of the plot. The constant C is not needed in the analysis.

[5] "Slide Rule for Routing Floods through Storage Reservoirs or Lakes," by C. J. Posey, *Engineering News-Record*, April 25, 1935, Vol. 114, p. 580.

[6] "Hydraulics of the Miami Conservancy District," by Sherman M. Woodward, Technical Reports of the Miami Conservancy District, Part VII, Chapter VII.

A similar procedure may be followed with the depth-area data, and the depth-capacity exponent found by integration of the empirical relation so determined. It is better, however, to determine the depth-capacity exponent directly, because integration of the empirical relation derived by logarithmic plotting is more likely to introduce error than numerical summation of the original survey data.

In studying the depth-capacity curves for more than 250 reservoir sites, m was found to vary from 1.03 to 4.74. The following classification, given by R. A. Sutherland, Assoc. M. Am. Soc. C. E., was found to be justified.[7]

Classification	Values of m
Lake type	1.0 to 1.5
Flood-plain and foothill type	1.5 to 2.5
Hill type	2.5 to 3.5
Gorge type	3.5 to 4.5

In almost all cases, the points lay very nearly along a straight line on the logarithmic plot. The use of the exponential formula to obtain capacities at higher levels than those for which survey data are available is inadvisable. For some sites, the logarithmic plot will follow a straight line over a considerable depth, and then deviate sharply to one side. For others, the points will lie on a curve. Since volumes near the bottom of the reservoir are relatively insignificant, it is important that the best straight line should fit the data at the higher levels most closely. If the straight line is a close approximation to the data at higher levels, discrepancies at the lower levels can be ignored, with inappreciable error in the results. Some judgment is required in deciding whether the degree of approximation is satisfactory. No rigid rule can be formulated. In doubtful cases a check should be made by the step method.

Equivalent Uniform Flood.—The equivalent uniform flood corresponding to a given irregular flood hydrograph is a flood of uniform intensity, having the same total inflow as the given flood, which will produce the same total amount of storage with the same maximum rate of outflow from the reservoir. It is possible to determine a uniform flood exactly equivalent to a given irregular flood by detailed routing computations. It has been found, however, that even for hydrographs differing considerably from rectangular, it is not difficult to select, arbitrarily, an equivalent uniform flood that will give results sufficiently accurate for design purposes. For example, consider the triangular flood shown in Fig. 1. This flood was routed by the step method through a reservoir (m = 2.5) with the orifice type of outlet. The maximum outflow reached was 5,160 acre-ft per hr and the maximum storage, 117,100 acre-ft.

---

[7] "Some Aspects of Water Conservation," by R. A. Sutherland, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 164.

If the duration T of an equivalent uniform flood is assumed to be 40 hr, the intensity I should be equal to the total volume of the flood divided by 40, or 7,320 acre-ft per hr. Routing this uniform flood through the reservoir by the step method the maximum rate of outflow reached was found to be 5,140 acre-ft per hr, which is very close to the value obtained for the triangular flood.

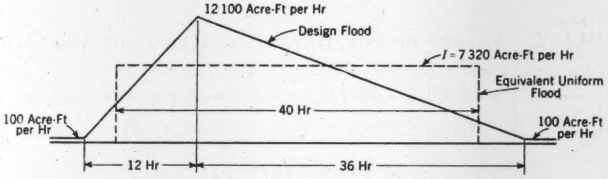

FIG. 1.—TRIANGULAR FLOOD AND EQUIVALENT UNIFORM FLOOD

The error in the maximum outflow rate and the maximum storage, corresponding to different assumptions for the duration of the uniform flood, is given in Table 1. It is seen that any estimate for the duration of the equivalent uniform flood between the values of 38 hr and 42 hr gives satisfactory accuracy, in this case. Similar results from other comparisons made by the writers confirm the belief that arbitrary selection of equivalent uniform floods is not difficult. It should be remembered that there is considerable uncertainty in the shape and volume of the "design" hydrograph.

TABLE 1.—ERRORS IN THE MAXIMUM OUTFLOW RATE AND MAXIMUM STORAGE

Duration assumption, T, in hours (1)	Inflow, I, in acre-feet per hour (2)	Maximum outflow rate, O, in acre-feet per hour (3)	Percentage error in maximum outflow rate (4)	Maximum storage, S, in acre-feet (5)	Percentage error in maximum storage (6)
38	7,700	5,195	+0.68	121,000	+3.3
40	7,320	5,140	−0.39	115,000	−1.8
42	6,970	5,080	−1.55	108,000	−7.8

Outflow Ratio.—The outflow ratio, x, is the ratio of the maximum outflow from the reservoir to the uniform inflow of the rectangular flood. It is the same as the "protection ratio" defined by Mr. Woodward.[6] The writers recommend that the name "protection ratio" be abandoned as misleading. The higher the value of this ratio, the greater the maximum outflow and the less the protection.

THE DETENTION RATIO

The detention ratio is the ratio of the maximum reservoir storage reached during the flood to the total volume of the uniform flood. By definition, then,

$$d = \frac{S}{I\,T} \qquad (2)$$

in which d is the detention ratio, S is the maximum storage, and $I\ T$ is the total volume of the uniform flood. The detention ratio is a function of the depth-capacity exponent, m, the outflow ratio, x, and the exponent governing the discharge of the outlets. The writers have computed values of d over the practical range of the outflow ratio and depth-capacity exponent, for reservoirs with orifice-type outlets (Table 2(*a*)) and for reservoirs with weir-type outlets (Table 2(*b*)). The values of d were computed with the aid of the infinite series developed in the Appendix. They can be checked (indirectly) by any of the standard step methods.

5.5	0.921	0.841	0.761	0.679	0.596	0.511	0.422	0.330
6.0	0.920	0.839	0.757	0.674	0.590	0.504	0.415	0.322

It is worth noting that for manually controlled outlets operated at 100% efficiency,

$$d = 1 - x \quad \text{(3)}$$

ILLUSTRATIVE EXAMPLES

The significance and utility of the detention ratio in the functional design of flood control reservoirs will be illustrated by two examples.

Example 1.—Find the relation between the maximum outflow and the storage required for controlling a flood of 50,000 acre-ft in 24 hr by an orifice-outlet reservoir at reservoir site A, Fig. 2. The depth-capacity exponent for this site is 2.25. The average inflow is $I = \dfrac{50{,}000}{24} = 2{,}080$ acre-ft per hr. The computations are shown in Table 3, the column headings of which are

TABLE 3.—COMPUTATIONS, EXAMPLE 1

Outflow ratio, x (1)	Maximum outflow, $O = x\,I$, in acre-feet per hour (2)	Detention ratio, d, from Table 2(a) (3)	Storage required, in acre-feet ($S = 50{,}000\, d$) (4)
0.4	835	0.668	33,400
0.5	1,040	0.582	29,100
0.6	1,250	0.496	24,800
0.7	1,460	0.406	20,300
0.8	1,670	0.312	15,600

self-explanatory. The curve showing the relation between the maximum outflow and the storage required can be plotted from the data in Columns (2) and (4).

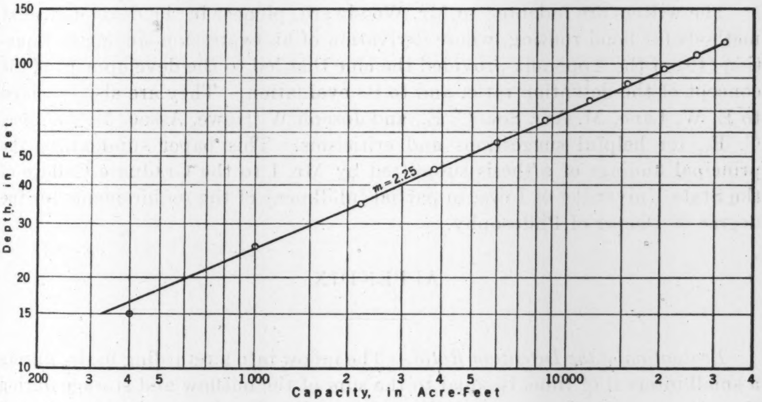

FIG. 2.—DEPTH-CAPACITY CURVE FOR RESERVOIR SITE "A"

Example 2.—Assume that, for the same example, political or other non-engineering reasons dictate that the maximum storage available shall be 25,000 acre-ft. What is the maximum flood reduction which may be obtained by the construction of a reservoir with an orifice type of outlet? By Equation (2), $d = \dfrac{25{,}000}{50{,}000} = 0.50$. From Table 2($a$)—for $m = 2.25$, and $d = 0.50$—$x = 0.595$. Hence, the maximum outflow $= x\,I = 0.595 \times 2.080 = 1{,}240$ acre-ft per hr. If the weir type of outlet is used instead of the orifice type, from Table 2(b)—for $m = 2.25$, and $d = 0.50$—$x = 0.725$. Hence, the maximum outflow $= 0.725 \times 2{,}080 = 1{,}510$ acre-ft per hr.

Manually-Controlled Outlets.—There has been much argument as to the relative merits of manually-controlled and automatic (fixed) outlet structures for flood control reservoirs. Comparisons based upon items as difficult to evaluate as fallibility should be postponed until the relative economy has been investigated. Tabulated values of the detention ratio afford an easy approach to such study. For example, assume that reservoir site *A* of Example 1 is to be used to reduce the maximum outflow from a flood of 50,000 acre-ft in 24 hr to 1,000 acre-ft per hr, and that the average cost of storage near the top of the reservoir is $30 per acre-ft. By interpolation in Table 3 the storage required, if orifice-type outlets are used, is found to be 29,900 acre-ft. With manually-controlled outlets, an efficiency of 100% could presumably be reached, in which case 25,900 acre-ft of storage would be required. The saving in storage is 4,000 acre-ft, representing $120,000. If manually-controlled outlets are to be economical, this $120,000 must exceed the capitalized cost of the maintenance and operation of the mechanical gates, plus or minus any difference in the original cost of the outlets.

ACKNOWLEDGMENTS

The writers are indebted to Mr. Woodward, pioneer in the development of methods for flood routing, whose derivation of an expression similar to Equation (19) of the Appendix provided the clue that led to the development of the concept of the detention ratio, and to its evaluation. They are also indebted to E. W. Lane, M. Am. Soc. C. E., and Joseph W. Howe, Assoc. M. Am. Soc. C. E., for helpful suggestions and criticisms. This paper summarizes the principal findings of a thesis submitted by Mr. I to the Graduate College of the State University of Iowa, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

APPENDIX

Evaluation of the Detention Ratio.—The inflow into a retarding basin, during a small interval of time, is equal to the sum of the outflow and storage during that interval of time, evaporation and percolation losses being neglected. Thus,

$$i\,dt = o\,dt + ds \qquad (4)$$

in which: i = average inflow rate during the time dt; o = average outflow rate during the time dt; dt = a small increment of time; and ds = increment of storage capacity during the time dt. The outflow from a reservoir can be expressed in terms of the depth h:

$$o = B\,h^n \qquad (5)$$

in which n is 0.5 for the orifice type of outlet, and 1.5 for the weir type. The storage capacity can be approximated by a monomial exponential function of the depth:

$$s = C\,h^m \quad \text{(1)}$$

so that

$$ds = C\,m\,h^{m-1}\,dh \quad \text{(6)}$$

Substituting these relations into Equation (4),

$$i\,dt = B\,h^n\,dt + C\,m\,h^{m-1}\,dh \quad \text{(7)}$$

For a constant inflow, I, during the entire flood period, Equation (7) becomes

$$I\,dt = B\,h^n\,dt + C\,m\,h^{m-1}\,dh \quad \text{(8)}$$

Transposing and collecting like terms,

$$dt = \frac{C\,m}{I}\left(\frac{h^{m-1}}{1 - \frac{B}{I}\,h^n}\right)dh \quad \text{(9)}$$

Equation (9) can be transformed into an infinite series by direct division,

$$dt = \frac{C\,m}{I}\left[h^{m-1} + \left(\frac{B}{I}\right)h^{m+n-1} + \left(\frac{B}{I}\right)^2 h^{m+2n-1} + \left(\frac{B}{I}\right)^3 h^{m+3n-1} + \cdots\right]dh \quad \text{(10)}$$

Integrating, term by term,

$$t = \frac{C\,m}{I}\left[\frac{h^m}{m} + \left(\frac{B}{I}\right)\frac{h^{m+n}}{m+n} + \left(\frac{B}{I}\right)^2 \frac{h^{m+2n}}{m+2\,n} + \left(\frac{B}{I}\right)^3 \frac{h^{m+3n}}{m+3\,n} + \cdots\right] \quad \text{(11)}$$

Substituting $o = B\,h^n$ and $s = C\,h^m$

$$t = \frac{s\,m}{I}\left[\frac{1}{m} + \left(\frac{o}{I}\right)\frac{1}{m+n} + \left(\frac{o}{I}\right)^2 \frac{1}{m+2\,n} + \left(\frac{o}{I}\right)^3 \frac{1}{m+3\,n} + \cdots\right] \quad \text{(12)}$$

At the end of the uniform flood, when the elapsed time has reached the value T, the storage of water in the reservoir will have attained its maximum value S, and the outflow rate its maximum value O. At this instant, Equation (12) becomes

$$T = \frac{S\,m}{I}\left[\frac{1}{m} + \left(\frac{O}{I}\right)\frac{1}{m+n} + \left(\frac{O}{I}\right)^2 \frac{1}{m+2\,n} + \left(\frac{O}{I}\right)^3 \frac{1}{m+3\,n} + \cdots\right] \quad \text{(13)}$$

If the ratio of the maximum outflow to the uniform inflow is denoted by x, the "outflow ratio," the total inflow during the flood period will be

$$I\,T = S\,m\left(\frac{1}{m} + \frac{x}{m+n} + \frac{x^2}{m+2\,n} + \frac{x^3}{m+3\,n} + \cdots\right) \qquad (14)$$

The total outflow during the reservoir-filling period, T, is equal to the total inflow minus the maximum storage,

$$\int o\,dt = I\,T - S = S\,m\left(\frac{x}{m+n} + \frac{x^2}{m+2\,n} + \frac{x^3}{m+3\,n} + \cdots\right) \qquad (15)$$

The average outflow during the period T is

$$\frac{\int o\,dt}{T} = \frac{I\left(\dfrac{x}{m+n} + \dfrac{x^2}{m+2\,n} + \dfrac{x^3}{m+3\,n} + \cdots\right)}{\left(\dfrac{1}{m} + \dfrac{x}{m+n} + \dfrac{x^2}{m+2\,n} + \dfrac{x^3}{m+3\,n} + \cdots\right)} \qquad (16)$$

The ratio, r, of the average outflow to the maximum outflow is given by

$$r = \frac{\dfrac{\int o\,dt}{T}}{O} = \frac{\dfrac{\int o\,dt}{T}}{x\,I} \qquad (17)$$

so that

$$r = \frac{\left(\dfrac{1}{m+n} + \dfrac{x}{m+2\,n} + \dfrac{x^2}{m+3\,n} + \cdots\right)}{\dfrac{1}{m} + x\left(\dfrac{1}{m+n} + \dfrac{x}{m+2\,n} + \dfrac{x^2}{m+3\,n} + \cdots\right)} \qquad (18)$$

By factoring and direct division the following expression is obtained, which gives the limiting value of r as x approaches zero:

$$r = \frac{m}{m+n}\left[1 + \frac{n^2\,x}{(m+n)(m+2\,n)} + \frac{(m^2 + n\,m + 2\,n^2)\,n^2\,x^2}{(m+n)^2\,(m+2\,n)\,(m+3\,n)} + \cdots\right] \qquad (19)$$

The detention ratio can be evaluated by substituting values of r into the equation

$$d = 1 - r\,x \qquad (20)$$

which follows from the definitions of d, r, and x. Equations (18) and (20) were used in computing the values of the detention ratio given in Table 2.

Time of Emptying.—The time required to empty a reservoir after the cessation of the uniform flood is found by letting the inflow equal zero in Equation

(8), which then becomes

$$\text{Zero} = B\, h^n\, dt + C\, m\, h^{m-1}\, dh \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

Transposing,

$$dt = -\frac{C\, m}{B}\, h^{m-1-n}\, dh \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

Integrating,

$$\int_T^t dt = -\frac{C\, m}{B} \int_H^h h^{m-1-n}\, dh \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

and,

$$t - T = \frac{1}{m-n}\, \frac{C\, m}{B}\, (H^{m-n} - h^{m-n}) \ldots\ldots\ldots\ldots (24)$$

except when $m - n =$ zero. From Equation (24),

$$t - T = \left(\frac{m}{m-n} \right) \frac{S}{O} \left[1 - \left(\frac{o}{O} \right)^{(m-n)/n} \right] \ldots\ldots\ldots (25)$$

The total time T' required to empty the basin after the uniform flood ceases is found by letting o equal zero in Equation (25) and therefore

$$T' = \left(\frac{m}{m-n} \right) \frac{S}{O} \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

DISCUSSION

Edward Soucek,[8] Jun. Am. Soc. C. E. (by letter).—A very convenient method for analysis of the action of flood control reservoirs with fixed outlets has been given by the authors. The selection of an equivalent uniform flood to represent a given non-rectangular inflow hydrograph may prove troublesome, despite the assurance of the authors that this operation is not difficult. A 40-hr uniform flood of equal total inflow is proved to be "equivalent" to the triangular flood shown in Fig. 1 for a particular outflow rate but no basis for the pre-selection of this duration is given. It seems that errors in estimates of the duration of the rectangular flood considerably exceeding those of 5% which are used in Table 1 are easily possible.

It is true that the paper deals primarily with the use of the rectangular flood—not its determination—so if it were not for the example given, this question would not be raised. The writer believes that the latitude which is possible in the establishment of the equivalent uniform flood is reduced if its total inflow is made equal to that of the hydrograph which is to be replaced only up to the time of maximum outflow. The inflow rate after this instant may remain constant indefinitely or may drop immediately to zero without effect upon either the maximum outflow rate or the maximum storage volume. It appears that the exclusion of an extraneous part of the inflow hydrograph makes the selection of a rectangular flood easier.

Considering the triangular hydrograph shown in Fig. 1, if a maximum outflow rate of 5,160 acre-ft per hr is contemplated, the maximum storage and outflow rate occur 32.8 hr after the beginning of the flood. The total inflow up to this time is 253,000 acre-ft. The remaining 40,000 acre-ft of inflow and the corresponding 15.2 hr of time are neglected. By plotting a mass curve of the given flood, the writer found that the least deviation of accumulated inflows between a rectangular hydrograph and the given inflow hydrograph resulted when the duration of the uniform flood was 31 hr and the intensity was 8,160 acre-ft per hr. By the application of Table 2, the maximum storage for this rectangular hydrograph was found to be slightly more than 116,000 acre-ft, a close check on the step-method solution. This elementary procedure may merely prove the contention of the authors that the selection of the equivalent uniform flood is easy but is intended to substantiate a preference regarding the total inflow of the uniform flood.

In Table 2, the small effect on the detention ratio of considerable variation in the depth-capacity exponent is very significant. Since the point of zero depth is fixed by the elevation of the outlets, a monomial exponential function cannot be fitted to the data as accurately as would be the case if the point of zero depth could be adjusted at will. This restriction is apparently unimportant except for high outflow ratios.

For orifice-type outlets, the depth-discharge exponent may be expected to remain sensibly constant at the value of 0.5. For weir-type outlets, however, the use of 1.5 for the depth-discharge exponent is somewhat in error, owing to the tendency for the constant B in Equation (5) to increase with the head. When only instantaneous discharges are being considered, the use of a constant exponent and a varying coefficient is justified by the resulting convenience of calculation. When a monomial exponential function with both the coefficient and exponent held constant is necessary, it might be better to modify the exponent. Assuming what appeared to be a reasonable variation of the coefficient B with the head, the writer plotted logarithmic rating curves for ogee spillways designed for 5-ft, 10-ft, and 20-ft heads and found that the exponent 1.6 represented the depth-discharge relation better than the exponent 1.5. The effect is smaller than might be anticipated from the variation in B which was used—a linear variation from 3.1 at zero head to 4.0 at the design head. As in the case of the depth-capacity exponent, the difference seems unimportant for low outflow ratios.

---

[8] Asst. Hydr. Engr., The Panama Canal, Diablo Heights, Canal Zone.

J. C. STEVENS,[9] M. AM. SOC. C. E. (by letter).—By substituting a uniform inflow for the variable inflow of the actual flood, the authors of this paper propose to simplify the problem of routing floods through reservoirs. This uniform inflow is selected by trial to have such a duration T that it will leave the same volume stored in the reservoir, and produce the same maximum rate of outflow as the actual flood event. It cannot determine any rate of outflow other than the maximum; yet other values of the outflow during the flood are frequently of considerable importance. Neither can it determine the time of occurrence of the actual outflow, which is generally of paramount importance.

The question arises as to whether the simplification resulting from this method of approach is not more apparent than real, and whether one might not solve the problem for the actual flood event in less time than that taken to find the "equivalent uniform flood," particularly if it is important to know the actual pattern of outflow.

For example, consider the basic relationship given in Equation (4). Since both the outflow o and the storage capacity s are single-valued functions of the depth above the outlet h, the latter may be eliminated from the equations and, therefore,[10] $s = f(o)$ from which

$$\frac{ds}{do} = f'(o) \qquad (27)$$

but $f'(o)$ represents the slope of the curve $f(o)$ at any given point. If a curve is plotted, or if a table of storage increments corresponding to outflow increments at various values of outflow is compiled, it is possible to obtain the function $f'(o)$ and, once for all, have the essential data to route any flood through that reservoir.

Let t = any finite time interval; i = average inflow during that interval; o_1 = outflow at the beginning of that interval; o_2 = outflow at the end of that interval; and θ = slope of the outflow-storage curve as previously explained for the average value of outflow during that interval; that is, $\frac{ds}{do} = f'(o) = \theta$.

---

[10] "Computing Reservoir Outflow and Height from Inflow and Capacity," by J. C. Stevens, *Engineering News-Record*, December 22, 1921, p. 1031, Equations 2 and 3.

It is well to fix the significance of θ well in mind. It merely means that for each cfs-increment (cfs = cubic feet per second) in outflow the storage increment is θ sfd (second-foot-day; increment may be either + or −).

* Midnight = 0. † In thousands of cubic feet per second.

Substituting Equation (27) in Equation (4)

$$i\,dt = o\,dt + f'(o)\,do \quad \text{(28)}$$

Equation (28) may be translated into the finite form

$$o_2 - o_1 + \frac{(o_2 + o_1)t}{2\,\theta} = i\,\frac{t}{\theta} \quad \text{(29)}$$

Solving for the outflow at the end of the time interval t:

$$o_2 = \frac{i}{\frac{\theta}{t} + \frac{1}{2}} + o_1 \frac{\frac{\theta}{t} - \frac{1}{2}}{\frac{\theta}{t} + \frac{1}{2}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

Starting with an initial outflow o_1, the outflow o_2 is found directly, which then becomes the o_1 for the next interval.

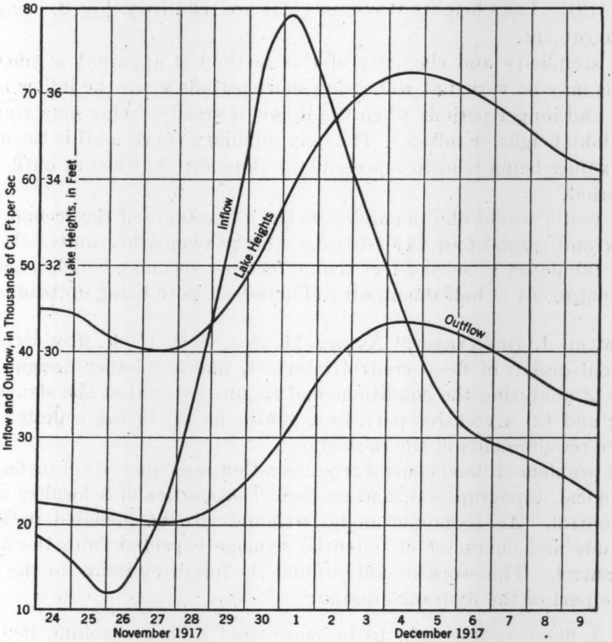

FIG. 3

The ease and rapidity with which this formula is applied in a step-by-step process, and the accuracy of the outflow pattern obtained thereby, rather obviate the necessity of trying to find an equivalent uniform inflow. This point so deserves emphasis that the writer believes an example of its application is warranted.

To illustrate, the flood of November-December, 1917, is routed through Coeur d'Alene Lake, Idaho. This lake forms the head of the Spokane River. At the outlet, a rating curve has been developed. The control is the 8 miles of river between the lake and Post Falls, Idaho. The storage capacity of the lake has been determined by surveys. The principal tributaries are the Coeur d'Alene and St. Joe rivers on which inflow was measured and a small percentage added for other tributaries. Table 4 gives the data necessary to route the flood. These data, with any given inflow, are all that is required to route any flood through this lake.

Table 5 shows the computations for routing the flood of November-December, 1917. The average inflow for each time interval in Table 5 was read from the inflow curve of Fig. 3. Values of θ were also read from Fig. 3, taken to the nearest 0.5 only. The outflow o_2 in Column (10), Table 5, is the sum of columns (8) and (9) and applies to the end of the periods indicated, the preceding value being the outflow o_1 at the beginning of the period as used in Column (9). Lake heights (Column (11)) are read from Fig. 3, using outflow as the argument.

The simplicity and elasticity of this method is apparent at once. Time intervals may be varied at will, using short periods when the inflow is varying rapidly and longer periods when the inflow is steady. One may start at any known lake height or inflow. The only auxiliary curve used is the θ-curve of Fig. 3, values being read to represent the slope for the average outflow during each period.

The writer would like to emphasize the advantages of the second-foot (cfs) for flow and second-foot-day (sfd) for storage over other units. Inflows are usually tabulated in second-feet (cubic feet per second), which avoids a conversion; also, sfd = half the number of acre-feet, both being units of volume.

EDWARD J. BEDNARSKI,[11] ASSOC. M. AM. SOC. C. E. (by letter).—The functional design of flood control reservoir, like any other design, is: (1) A process of analyzing the conditions and requirements that the structure must satisfy; and (2) a creative part, or a synthesis, producing a design that will fulfil the requirements of the problem.

The problem of flood control requires a thorough analysis of meteorological, hydrological, topographical, and geological properties of a locality in need of flood control. An economic analysis should also be included regarding the magnitude and character of potential damage expected from the absence of flood control. This work should produce the following items for the use in the creative part of the hydraulic design:

(1) A flood hydrograph, to be considered as a controlling factor of the design;

(2) A maximum rate of runoff within the watershed of the locality which could be tolerated under existing, or properly improved, conditions; and

(3) The topographic and economic data pertaining to every possible reservoir site in the form of elevation-capacity curves and the highest allowable water elevation.

The problem confronting the designer is the selection of a site for a reservoir which satisfies the foregoing stipulations and, if it does, the determination of the size and the type of the outflow facilities.

The authors present a method based on a mathematical treatment of a differential formula (Equation (4)). In order to do so they disposed of the equation

---

[11] Structural Engr., Los Angeles, Calif.

$$i = f(t) \qquad \text{(31)}$$

assuming that it can be substituted by

$$I = \frac{\int_0^T i\,dt}{T} \qquad \text{(32)}$$

an average rate of inflow. The outflow, however, is considered variable, starting from zero; then it reaches a maximum Q which is not supposed to be larger than I. Contrary to the notation of the paper the writer uses q and Q instead of o and O, respectively.

Unfortunately the writer has met with a number of cases in which $\frac{Q}{I}$ was greater than 1.

In the light of experience it appears quite futile to attempt a mathematical solution of the problem. A better approach seems to be a study of Equation (31) as it is represented by a hydrograph, in the form of Equation (32), or a mass curve that can be obtained from the hydrograph by numerical or graphical summation.

Quite contrary to the assumptions of the authors are the conditions of the problem to determine the least possible constant rate of outflow for a given amount of storage. Here q is constant but i is variable; and in Equation (5) $n = 0$ and $q = Q$, ($q = B\,h^n$).

This problem is solved easily, as follows: Consider the mass curve (a) shown in Fig. 4. Draw the same mass curve (upper part of it) downward from the first by a distance numerically equal to the maximum available storage (curve (b)). A straight line between these two curves tangent to each (see curve (c)) solves the problem. The tangent of the angle that this line makes with the horizontal axis, expressed in terms of acre-feet-per-hour yields the answer. The diagram is self-explanatory.

The foregoing solution is applicable when the outlet conduits are so located as to have sufficient head to pass the required discharge when storage in the reservoir is assumed to be equal to zero. However, if a certain initial storage is required to build up the necessary head, the second mass curve (b) should be drawn below the first by a distance equal to the difference in storage between the required initial and the maximum available storage. A straight line (c) tangent to these two curves will again produce the solution of the problem.

The problem of spillway length and the elevation of the spillway crest cannot be solved so simply. The outflow is not constant any more and all that is known about the outflow mass curve is that it is tangent to the mass curve or the horizontal axis at the time t_0, and parallel with the tangent to the mass curve at t_e, the time when the outflow is expected to be equal to the inflow. Between these two points the curve has no point of inflection and the angle of the tangent to this curve at any point is smaller than a tangent to the inflow mass curve at the same time. With some practice, it is possible to predict whether there is any possibility of designing an ordinary spillway with a given

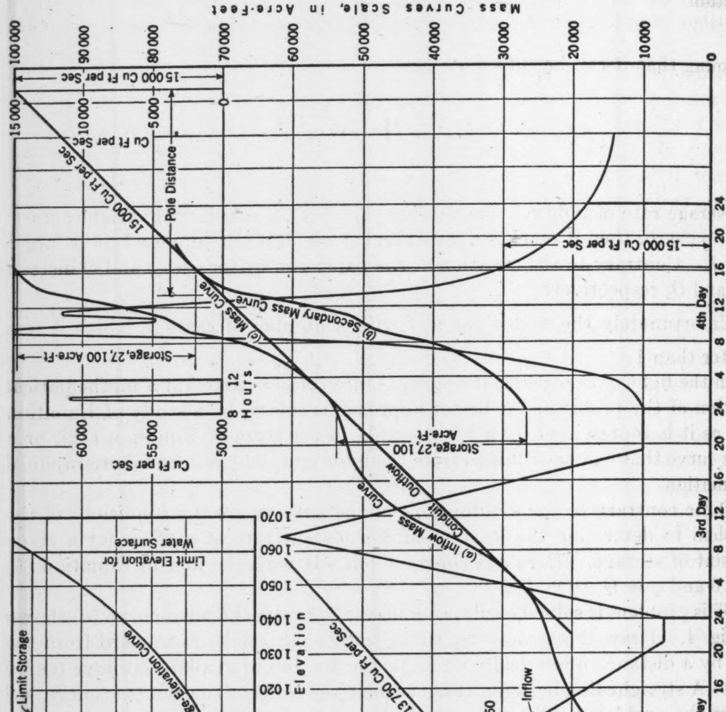

FIG. 4.—TO DETERMINE THE LEAST POSSIBLE CONSTANT RATE OF OUTFLOW FOR A GIVEN QUANTITY OF STORAGE

highest permissible elevation of the water surface and the elevation of the spillway crest.

Using Equations (1) and (5) it is possible to determine the necessary length of the spillway crest embodied in the constant B, as follows:

$$B = \left(\frac{C}{S}\right)^p Q \qquad (33)$$

in which (to simplify typography) $p = \frac{n}{m}$. This may or may not be the solution.

Whether the spillway length thus determined is satisfactory could be found by means of mass and storage-elevation curves by arithmetical computation or graphically.[12] Evidently there is no general solution. Each case must be solved by trial and error, which is not unusual and many, if not most, engineering problems are solved in this manner.

The limits of this discussion do not permit a detailed description as to the use of mass and storage-elevation curves in order to save some of the drudgery connected with the hydraulic design, and the writer regrets to state that an ingenious idea of using an average value of the inflow rate (as suggested by the authors) does not relieve the designer from a mass of tedious and painstaking labor, unavoidable in the process of the solution by trial and error.

Roland A. Kampmeier,[13] **Jun. Am. Soc. C. E.** (by letter).—This interesting and worth-while paper extends the principle of Mr. Woodward's "five-sixths rule"[3] to a wide variety of possible reservoir conditions.

The "five-sixths rule" states that the ratio, r, of average outflow to maximum outflow, will be approximately five-sixths under certain conditions—namely, when the reservoir has an orifice-type outlet; when the exponent, m, in the depth-capacity relationship is approximately 2.5; and when the ratio, x, of maximum outflow to assumed constant inflow is not too large. From Table 2 and Equation (20) it may be determined that their cases cover a range of values of r from 0.67 to 0.94 for the orifice-type outlet and from 0.41 to 0.85 for the weir-type outlet, the lowest values of r corresponding to the lowest values of m and of x. The effect of m is much more pronounced than the effect of x.

It may be noted that the use of weir-type outlets, to the exclusion of orifice-type outlets, would be unusual among reservoirs for flood control only (to the discussion of which the paper is limited), and that the paper indicates that the "five-sixths rule" is fairly satisfactory for orifice-type outlets when m is in the usual range of 2.0 to 3.5, and when x is less than about 0.6 (which would probably be the usual case in reservoirs designed exclusively for flood control).

Since the effect of the exponent m on the ratio r is so pronounced, it may be useful to emphasize that for a given reservoir the same value of m would not be likely to apply in comparing orifice-type and weir-type outlets. A weir-type outlet, or spillway, would normally be placed at a considerably higher level than orifice-type outlets, or sluices. If Equation (1) represented the depth-capacity relationship above the level of the sluices, the depth-capacity relationship above a higher spillway level could be represented approximately by a similar equation only if a smaller value of m were used. It would be interesting to know whether the values of m between 1.03 and 4.74, found by the authors for more than 250 reservoirs, were based on the depth-capacity relationships above sluice or spillway levels, as the case may be (as might be assumed from the applications in this paper), or above the bottom of the reservoirs, applying the equation as used by Mr. Sutherland.[7]

Bednarski, *Western Construction News*, February 25, 1932, p. 113 (see also erratum, *loc. cit.*, March 25, 1932, p. 168).

[13] Associate Prof., Hydr. Eng., Univ. of Tennessee, Knoxville, Tenn.

The authors mention (but do not discuss in detail) their method of selecting an equivalent uniform flood to replace the assumed design hydrograph, a method which differs from that used by Mr. Woodward,[6] who considered only that part of the hydrograph preceding the instant when the outflow equals the inflow and the maximum storage capacity has been reached. The authors' example (see Fig. 1) does not indicate whether or not a shorter equivalent flood of greater intensity would have been used if less storage capacity had been assumed available. The impression is left with the writer that the authors would use the same equivalent flood for all assumed conditions of outlet size and storage capacity. Suppose that the maximum outflow in the case indicated in Fig. 1 were 8,050 acre-ft per hr; using the equivalent flood shown would mean assuming an apparently unsatisfactory value of x of 1.1.

The writer questions whether the authors have used properly Mr. Woodward's term, the "protection ratio," which they state to be the same as their "outflow ratio," x, the ratio of the maximum outflow to the uniform inflow of the equivalent flood (see "Introduction: Outflow Ratio"). The writer understood the original use of the term "protection ratio" to mean the ratio of the maximum flood inflow to the maximum outflow,[14] whereas the term "outflow ratio" was originally used[15] with a different meaning than that assigned to it by the authors.

Appreciation of the data presented is obscured by the fact that the term x, in Table 2 and in Equation (3), does not reflect the actual reduction in maximum discharge. It might have been desirable to use values of the "protection ratio," as the writer understands its meaning, as headings of the columns in Table 2, instead of the values of the authors' "outflow ratio." The writer realizes that the use of the protection ratio would require assumptions as to the shape of the hydrograph. The isosceles-triangle form of hydrograph would seem to be a reasonable assumption somewhat more similar to the true hydrograph in most instances than the equivalent rectangular flood.

EDGAR E. FOSTER,[16] ASSOC. M. AM. SOC. C. E. (by letter).—The authors have undertaken to furnish a much-needed means of analyzing problems arising in regard to the functional design of reservoirs. There are three general problems to solve in functional design—namely,

[14] "Hydraulics of the Miami Conservancy District," by Sherman M. Woodward, Technical Reports of the Miami Conservancy District, Part VII, Chapter VII, Fig. 73, p. 197.

[15] *Loc. cit.*, p. 200.

[16] Associate Engr., U. S. Engr. Office, Omaha, Nebr.

(*a*) Design flood; that is, the magnitude and hydrograph of a flood upon which the operation of the reservoir is to be based;
(*b*) Outflow attainable; and
(*c*) Capacity needed to obtain the desired measure of control.

The reservoir design flood is built upon the quantity of rainfall in a suitable storm, by means of distribution factors; or it is derived from a selected flood (perhaps the maximum) experienced on the watershed. In any case, it is based upon conditions not touched upon by the authors' paper and hence need not be discussed further herein. The reduction of outflow (Problem (*b*)) and storage required (Problem (*c*)) are the questions with which the authors deal. These two factors are reciprocal in that when one is given the other may be obtained.

The problem of the reduction of outflow may be decided from the channel-carrying capacity below the reservoir, or some other critical point downstream. Under these circumstances there remains the problem of determining how much capacity is needed to reduce the design flood to the desired maximum outflow. On the first glance it seems that the authors had provided a method to yield the answer. Unfortunately, however, it is not possible to find the "equivalent rectangular" flood as readily as is indicated in the paper. The only sure method of determining the equivalent rectangular flood is that of routing the design flood through the reservoir; and, when that is done, the required capacity is known, and it becomes unnecessary to apply the method, since all elements are then known.

The writer made an attempt to determine the capacity of a reservoir under investigation by the authors' method. The pertinent data for the reservoir are as follows: Reservoir design flood, peak discharge, 32,400 cu ft per sec; volume, of flood, 311,000 acre-ft; total duration, of flood, 12 days; outlet discharge fixed at 10,000 cu ft per sec; total capacity of reservoir, 545,000 acre-ft; and m, derived from the capacity curve, 3.15. The problem is to fix the capacity to be set aside for flood control in order to reduce the design flood from 32,400 to 10,000 cu ft per sec.

On the basis of a 12-day period, the equivalent rectangular flood is 13,000 cu ft per sec, from which $x = 0.77$. Then from Table 2, by interpolation, $d = 0.316$. The capacity needed, therefore, should be $0.316 \times 311{,}000$ or 98,000 acre-ft. However, by routing this flood through the reservoir, it was found that approximately 150,000 acre-ft were needed. An attempt was made also to utilize the time (6.2 days) during which the design flood was above the maximum outlet discharge. This duration of the rectangular flood required a storage capacity of 202,000 acre-ft.

In the foregoing example (which is typical of reservoir design floods), there is no period other than the full duration of the design flood that can be taken logically as the length of the equivalent rectangular flood. That period is too long, however, and its use does not provide sufficient storage. The time may be diminished continuously with increasing requirements for storage, but there is no way of determining the correct volume without routing through the reservoir. There seems to be no logical point on the hydrograph, therefore, at which the length of the equivalent rectangular flood can be fixed.

In certain cases it may be desirable to reverse the procedure of the foregoing example. The volume of storage available may be fixed, instead of the permissible outlet discharge, and the problem is then to determine the maximum reduction. This problem also requires the calculation of the quantity x; hence, the difficulty of the equivalent rectangular flood is met again.

It is highly desirable to start from the known factors of a problem and to work progressively toward a solution without resorting to trial methods; but it is apparent that the difficulty of the equivalent design flood prevents such a course in analyzing flood storage capacity with the authors' method.

Sherman M. Woodward,[17] M. Am. Soc. C. E. (by letter).—An enlightening, interesting, and useful extension of the methods used about 1915 in the design of the reservoirs of the Miami Conservancy District at Dayton, Ohio, is presented in this paper. At that time the so-called "five-sixths rule" was finally developed by the engineering staff of the District after a prolonged period of studying and puzzling over the various complex relationships involved in the determination of the required capacity of the several reservoirs and the dimensions of their respective outlets. It was recognized that no great virtue or precision should be attached to the exact numerical value, five-sixths, and that this coefficient should be expected to change with circumstances and should be checked in each important case by further detailed calculations.

The practical value of the "five-sixths rule" is that for the purpose of approximate estimates and comparisons in preliminary design, before dimensions are finally fixed, it gives results in a few minutes which would otherwise be obtained only after days of laborious computation. The rule was evolved as a result of a determined effort to discover a general, broad-visioned, practical method of approach to a complicated problem, an approach which should give due consideration to the main, essential factors and at the same time minimize the unimportant, non-essential factors.

The authors have performed a valuable service in throwing new light upon some of the relationships. The writer believes that the possibilities of the subject have not yet been exhausted and hopes that one effect of the paper will be to reveal new directions for further profitable exploration.

One item of particular importance in the paper is the direct comparison that can now be made between the relative advantages of the use of automatic versus manual-controlled reservoir outlets.

M. Kindinger,[18] Assoc. M. Am. Soc. C. E. (by letter).—Table 2 can be condensed to a single set of data by tabulating d against $\frac{n}{m}$ instead of m. Its use will then be extended to a wide range of outlet types besides those of the orifice and weir.

---

[17] Chf. Water Control Planning Engr., TVA, Knoxville, Tenn.

[18] Res. Engr., Umgeni Water Scheme, Durban, Union of South Africa.

In Equation (5), substituting the value of h determined from Equation (1), and considering o and s to be maxima,

$$O = \frac{B\,s^u}{C^u} \qquad \text{(34)}$$

in which (to simplify typography), $u = \frac{n}{m}$. An inspection of Table 2 will reveal that for the same values of u and x the detention ratio is identical in both sets, as demonstrated for a few values of u in Table 6.

TABLE 6.—VALUES OF m AND d COMPARED WITH TABLE 2

$u = \frac{n}{m}$	m		d			
	$n = 0.5$	$n = 1.5$	$x = 0.2$	$x = 0.4$	$x = 0.6$	$x = 0.8$
0	...	...	0.800	0.600	0.400	0.200
0.1	5	15	0.818	0.635	0.450	0.258
0.2	2.5	7.5	0.832	0.662	0.488	0.303
0.5	1	3	0.864	0.722	0.570	0.399
1.0	0.5	1.5	0.896	0.789	0.656	0.498
1.5	0.33	1.0	0.916	0.822	0.710	0.567
2.0	0.25	0.75	0.939	0.849	0.749	0.619

The formulas given in the Appendix can be converted by substituting u for $\frac{n}{m}$. For example, Equation (19) then becomes:

$$r = \frac{1}{1+u}\left[1 + \frac{u^2\,x}{(1+u)\,(1+2\,u)} + \frac{(1+u+2\,u^2)\,u^2\,x^2}{(1+u)^2\,(1+2\,u)\,(1+3\,u)} + \cdots\right] \qquad \text{(35)}$$

The statement that the equivalent uniform flood can be selected readily on an arbitrary basis is open to question. The close agreement shown in Table 1 is not a convincing demonstration because it is always possible to compute the exact equivalent uniform flood which, for any flood volume one wishes to choose, will give the same storage and peak outflow as the original: $x = \frac{O}{I}$; and (if V is the flood volume) $I = \frac{V}{T}$. Therefore,

$$T = \frac{x\,V}{O} \qquad \text{(36)}$$

In the authors' example $d = \frac{117{,}100}{292{,}800} = 0.40$; but interpolating from Table 2, $x = 0.697$ and, therefore, $T = \frac{0.697}{5{,}160} \times 292{,}800 = 39.4$ hr. The problem most common in practice, however, is the reverse one. The engineer must guess, or otherwise determine, T first, and then use its value to compute the value of d required to reduce the peak outflow to a particular magnitude.

It is clear that with outflow peaks near to, or greater than, 7,320 acre-ft per hr the 40-hr equivalent will give unreliable results. Evidently, therefore, T must be so chosen as to give an equivalent flood intensity I greater than the peak outflow; and hence, T will vary from case to case.

Furthermore, the peak outflow is not influenced in any way by that part of the flood curve that lies beyond the point of equalization (the point where outflow equals flood inflow and where, also, the outflow is at its peak). Hence, no apparent purpose is served by the condition that the equivalent uniform flood shall have a volume equal to that of the entire flood. Rather, it would appear to be advantageous if the volume of the equivalent were made equal to that of the inflow or flood at the point of equalization.

In studying flood routing problems the writer has found that the mass curve is far more serviceable than the intensity curve.

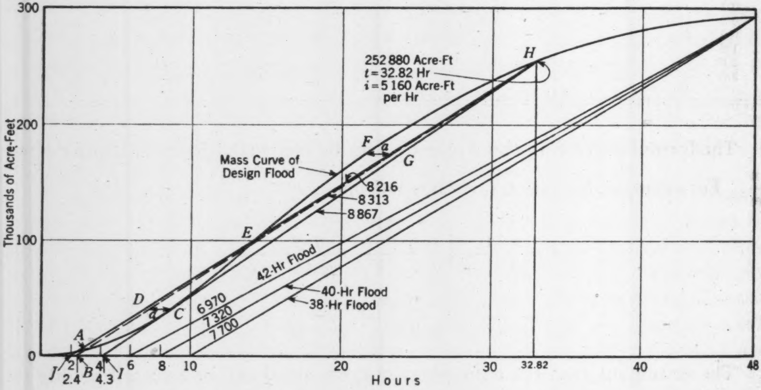

FIG. 5.—MASS CURVES OF VARIOUS SUBSTITUTE UNIFORM FLOODS COMPARED WITH MASS CURVE OF DESIGN FLOOD

In Fig. 5, which is a plot of the authors' example, H is the point of equalization. The storage volume will depend upon the shape and dimensions of the part of the curve $O\ C\ E\ F\ H$. Obviously, any equivalent uniform flood should deviate from this curve as little as possible. Starting from the known value of S and computing T, omitting the volume of inflow after the point of equalization, the period of the exact equivalent is found to be 30.8 hr. It is shown in Fig. 5 by the full line $J\ H$.

The following rule enables a substitute uniform flood curve to be drawn which will fit the original closely and yet give a value of the storage S which errs on the side of safety:

> Draw the chord $B\ H$, shown dotted, in such a manner that both the length of intercept, $H\ E$, and the horizontal divergence, $F\ G$, of the convex

part are respectively equal to, or larger than, the corresponding intercept, *E A*, and divergence, *D C*, of the concave part.

It can be proved, or verified by means of any of the step methods, that:

(*a*) A part of a mass curve concave upward gives a lesser flood-reducing effect than the chord joining its extremities and that the reverse is the case for a convex curve (it will be realized that the greater the increment in storage required to deal with the increment of the flood volume represented by the part of the flood curve in question the smaller will be the flood-reducing effect); and

(*b*) This difference in flood-reducing effect between chord and curve increases with length of chord, amount of divergence, and rate of outflow.

Even if the concave part, *A C E* (except for its reversed position), were identical in shape and dimension with the convex part, *E F H*, the larger outflow prevailing during the latter (convex) period would result in a greater difference in flood-reducing effect between chord and curve than would obtain during the earlier concave period. In addition, the flatter slope of the part, *O A*, in the beginning is superior in flood reduction to the chord *B A*. Hence, taking the substituted chord as a whole, it will have a lower flood-reducing effect than the original. In other words, it requires a higher storage *S* to reduce the peak to *O*. Another substitute that is easier to draw but has the disadvantage of giving a still more conservative result is the chord *I H* (Fig. 5), which is tangent to the concave part. For the purpose of comparison, computations have been made for $\frac{n}{m} = w = 2.0$, which gives a value of *u* at the opposite end of the field to that covered by the authors' $\frac{n}{m} = \frac{0.5}{2.5} = 0.2$. Storage *S* was determined graphically for the original flood and, for each of the uniform flood substitutes, by computation utilizing Tables 2 and 6. The results are summarized in Table 7.

TABLE 7.—COMPARISON OF MAXIMUM STORAGE FOR VARIOUS SUBSTITUTE UNIFORM FLOODS

Line	Type (see Fig. 5) (1)	*I* (2)	*O* (3)	*V* (4)	*x* (5)	*u* = 0.2		*u* = 2.0	
						d (6)	*S* (7)	*d* (8)	*S* (9)
1	Original	12,100	5,160	252,880	0.426	0.463	117,100	0.708	179,000
2	*J H*	8,216	5,160	252,880	0.628	0.463	117,100	0.733	185,300
3	*B H*	8,313	5,160	252,880	0.621	0.469	118,600	0.737	186,400
4	*I H*	8,867	5,160	252,880	0.582	0.504	127,440	0.759	191,900
5	44-hr	6,688	5,160	292,800	0.772	0.329	96,400	0.639	187,100
6	40-hr	7.320	5,160	292,800	0.705	0.392	114,800	0.688	201,500
7	36-hr	8,150	5,160	292,800	0.635	0.456	133,500	0.729	213,500

Arbitrary selection of the equivalent flood can lead to great uncertainty. Thus, in line 5, Column (7), Table 7, a 10% variation in *T* results in a negative error of nearly 19% in *S*, whereas line 7, Column (9), shows that a similar variation in the opposite direction involves a result 19% too high. The substitute uniform flood drawn according to the foregoing rule shows positive errors of less than 5%.

P. **Wilhelm Werner**,[19] Assoc. M. Am. Soc. C. E. (by letter).—This interesting study is valuable for the investigation of an important type of storage problem. It must be borne in mind, however, that it is strictly applicable only under certain conditions. For instance, if the reservoir outlet consists of a tunnel of some length, the discharge rating curve cannot be expressed, even approximately, by a monomial exponential function such as Equation (5). In the case of a pure orifice outlet the tailwater may sometimes influence the discharge so as to cause a considerable deviation of the rating curve from the monomial exponential function.

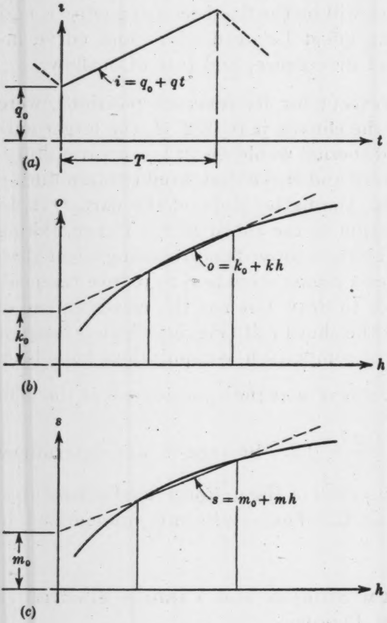

FIG. 6

As stated by the authors, flood routing studies are commonly executed by the trial-and-error step method or the integration method. In many cases, however, a combination of the two methods is useful. One such combination (which might be called the "straight-lines integration method") may be of interest in this connection. In its application this method is of the functional type, the integration, however, being executed in steps over a number of straight lines covering, as nearly as practicable, the given characteristic curves. Using the same nomenclature as the author, as far as possible, the procedure may be demonstrated as follows.

The inflow may be written

$$i = q_o + q\,t \qquad (37)$$

in which q_o is the intercept on the i-axis and q the slope of the straight line representing the inflow intensity during the interval T (see Fig. 6(*a*)). The outflow may be written

$$o = k_o + k\,h \qquad (38)$$

in which k_o is the o-intercept and k the slope of the straight line, substituting the outflow intensity curve in the part under consideration (see Fig. 6(*b*)).

---

[19] Civ. Engr., A. B. Vattenbyggnadsbyran, Stockholm, Sweden.

The depth-capacity may be written

$$s = m_o + m\,h \qquad (39)$$

in which m_o is the s-intercept and m the slope of the straight line to be substituted for the considered part of the depth-capacity curve (see Fig. 6(c)).

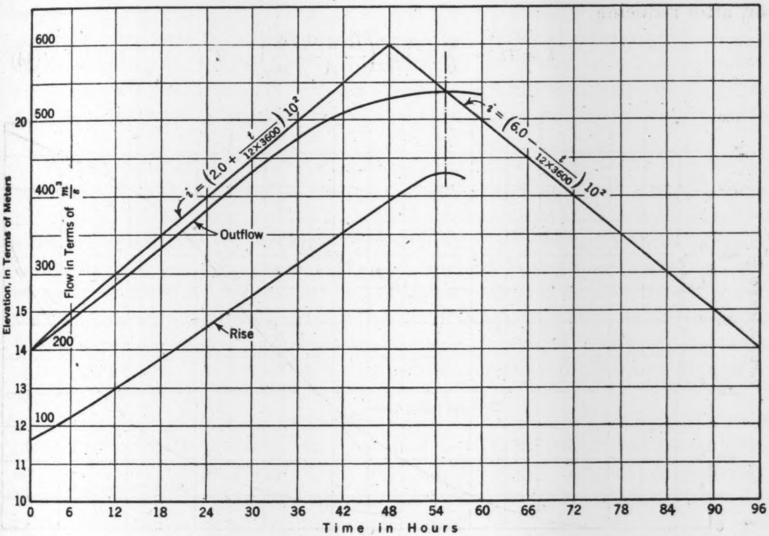

FIG. 7.—INFLOW HYDROGRAPH

Substituting Equations (37), (38), and (39) in the general differential equation (Equation (4)), and reducing:

$$m\frac{dh}{dt} + k\,h = q\,t - (k_o - q_o) \qquad (40)$$

Of the constants, q_o, m, and k are always positive, whereas q and k_o may be either positive or negative. If $t = o$ and $h = h_o$ are corresponding values, after integrating Equation (40), and reducing:

$$h - h_o = -\,(B + h_o)(1 - e^{-\alpha}) + A\,t \qquad (41)$$

in which (to simplify typography) $\alpha = \frac{k}{m}\,t$; and

$$A = \frac{q}{k} \qquad (42a)$$

and

$$B = \frac{1}{k}(k_o - q_o + m\,A) \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (42b)$$

If a theoretical maximum occurs in some interval, it is determined thus:

$$\frac{dh}{dt} = -\,(B + h_o)\,\frac{k}{m}\,e^{-\alpha} + A = 0 \;\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

or, after reducing,

$$t = t_m = \frac{m}{k} \times \log\left(\frac{B + h_o}{A}\,\frac{k}{m}\right) < T \;\ldots\ldots\ldots\ldots\ldots (44)$$

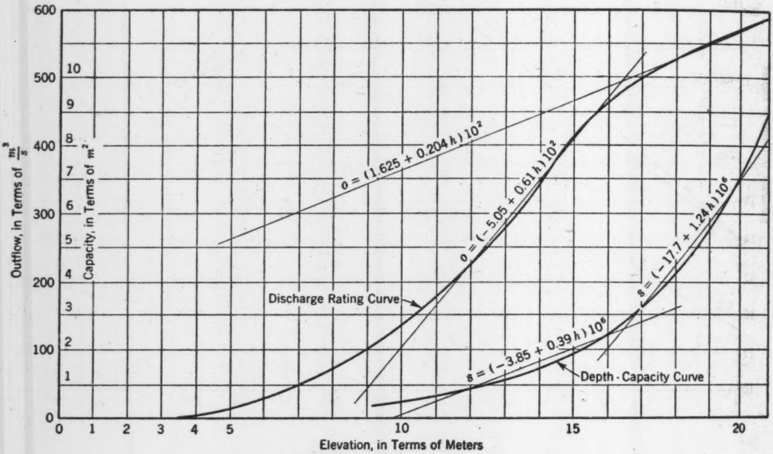

FIG. 8.—DISCHARGE RATING CURVE AND DEPTH-CAPACITY CURVE

The application of the foregoing deductions may be illustrated by the following example: The rise of the water level in a reservoir is to be determined for the flood given by the inflow hydrograph in Fig. 7. The water discharges through a by-pass tunnel, the discharge rating curve of which is shown in Fig. 8. The depth-capacity curve is also given in Fig. 8.

TABLE 8.—COMPUTATION OF RISE IN A RESERVOIR

h_o	q_o	q	k_o	k	m	A	B	$B + h_o$	$h - h_o$	$\frac{t}{3,600}$	h
11.60	200	$\frac{1}{432}$	−505.0	61.0	390,000	$\frac{1}{26,300}$	−11.3	+ 0.3	4.80	37.3	16.40
16.40	511	$\frac{1}{432}$	+162.5	20.4	1,240,000	$\frac{1}{8,820}$	−10.15	+ 6.25	1.45	10.7	17.85
17.85	600	$-\frac{1}{432}$	+162.5	20.4	1,240,000	$-\frac{1}{8,820}$	−28.35	−10.5	0.70	7.1*	18.55

* This value computed by means of Equation (44).

The computations, in three main steps, are summarized in Table 8, and the result is shown graphically in Fig. 7. A check by means of the usual trial-and-error step method shows a close agreement, the discrepancy in the total rise amounting to about 2%.

In comparison with the functional method developed by the authors, the foregoing suggestions possess the advantage of being applicable with sufficient accuracy to any storage problem of the nature in question, including all types of reservoirs and outlets. It also avoids the uncertainty in estimating the equivalent uniform flood. Compared with the trial-and-error step method it effects a saving in time and labor, inasmuch as the tedious cut-and-try operations have been eliminated. For office use a graphical evaluation of Equation (41), in some form or other, is often very helpful.

WALDO E. SMITH,[20] M. AM. SOC. C. E. (by letter).—An interesting contribution to the study of the functional design of reservoirs for flood control is found in this paper. Often the time-saving features of this method of establishing tentative basic values for a reservoir for preliminary estimates and as a guide in design have been overlooked, and it is hoped that this reminder of earlier studies will serve to call attention to this method of approach. However, the construction of gate controls on outlet works is the current tendency for flood control dams, and with this type of outlet, functional analysis loses much of its significance. It may still serve, none-the-less, on preliminary studies to give the value of the minimum allowable size of outlet.

The authors have failed to recognize the most common justification for the use of gate or mechanically controlled outlets. They assume that such outlets are for the purpose of maintaining 100% "efficiency," meaning, presumably, that outflow is uniform from the beginning to the end of the flood. The writer believes that this is incorrect usage of the term "efficiency" unless the only area one is attempting to protect from floods is that immediately below the dam. Ordinarily, one must relieve a prospective flood situation at some point or points considerably downstream, and must vary the outflow to accommodate the uncontrolled inflow into the channel at points between the control works and the points being protected. It is to provide for this needed flexibility that gate controls are ordinarily used. To quote from the Official Plan for the Muskingum Watershed Conservancy District:[21]

> "*Reasons for Selection of Gate Controlled Reservoirs.*—Careful study of the tributary arrangement of the Muskingum River and the time of travel of past flood crests on the tributaries show that the use of retarding basins will not provide either as efficient or as economical flood control as will gate controlled reservoirs. The principal objection to the retarding basin scheme as applied to the tributaries of the Muskingum River is based on the design principle of the system, that is, that the maximum outflow from any reservoir during the design flood must not, when combined with the outflow from other reservoirs and/or flows from uncontrolled areas, cause flows in excess of those for which provision has been made at any point downstream. * * * With gate control, the outflow from the reser-

[21] "Official Plan for the Muskingum Watershed Conservancy District," Vol. I, pp. 23 and 24.

voirs can be reduced during high discharge from uncontrolled areas and increased after the rate of runoff below the reservoirs has receded."

In discussing the depth-capacity exponent, m, the authors state that depths above the outlet location are used, whether the outlet is an orifice or a weir. It has been the writer's procedure to base this value, and the resulting exponential equation, on the height above approximate zero reservoir capacity, as explained by Professor Woodward for the case of variable depth.[22] In all instances that the writer can recall, it has been possible to make nearly all of the points fall very close to a straight line on logarithmic paper. The resulting equation in the form:

$$s = C\,h^m \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

has the advantage of defining the storage accurately throughout the depth of the reservoir. For general purposes, the method suggested by the authors has two undesirable results: First, it has the tendency to change the natural valley characteristics as indicated by m and C; and second, it frequently results in a plotting of points that does not approach a straight line, with the result that no satisfactory equation can be written.

Pleasant Hill Reservoir in Ohio is a case in point. There a weir-orifice outlet will maintain the water surface at an elevation of about 1,020 ft, nearly 50 ft above the channel bottom. Fig. 9 shows the depth-capacity curves based on the value of approximate natural zero capacity and based on Elevation 1,020. The uppermost plotting was the first attempt, based on an estimated zero capacity at Elevation 968. A second attempt, not shown, was made before arriving at the second line from the top. This straight line passes very close to all points, with zero capacity at Elevation 973. The formula for this curve is expressed by Equation (1), with $C = 0.29$ and $m = 2.80$. It serves capacity needs throughout the entire depth of the reservoir as well as of any part in which one might be especially interested, and m and C serve as correct indications of morphological conditions within the valley, as mentioned by the authors.

Using only that portion of the reservoir capacity above Elevation 1,020 and measuring depth from that elevation. a third plotting of points is shown. These do not follow a straight line. If one uses the equation of the tangent at the upper end of the curve defined by the points, $C = 180$ and $m = 1.58$, values of capacity determined in the vicinity of the highest elevation will be quite satisfactory; but nearer to the weir-orifice level, the values will serve no purpose. If one derives the equation of the secant, drawn through the uppermost and lowermost points shown—$C = 590$ and $m = 1.29$—in the vicinities of these two points values of total storage may be approximated, but intermediate values and differentials will have little significance. As demonstrated subsequently, the value of m for the entire reservoir gives a better value of maximum outflow, in this case, than either of the other two values determined. It should be noted that the characteristics of the valley apparently change

---

[22] "Hydraulics of the Miami Conservancy District," by Sherman M. Woodward, Technical Reports of the Miami Conservancy District, Part VII, pp. 118–121.

markedly, *m* changing from 2.80 (hill type) to 1.58 (flood-plain foothill type) to 1.29 (lake type). Possibly the latter value has some use in expressing the nature of the valley between two given horizontal planes; but by taking other than the natural zero of storage capacity, the measure of natural valley characteristics expressed in *m* and *C* is destroyed. That this acts likewise for other reservoirs is shown by reference to Table 9 for Senecaville Reservoir in Ohio.

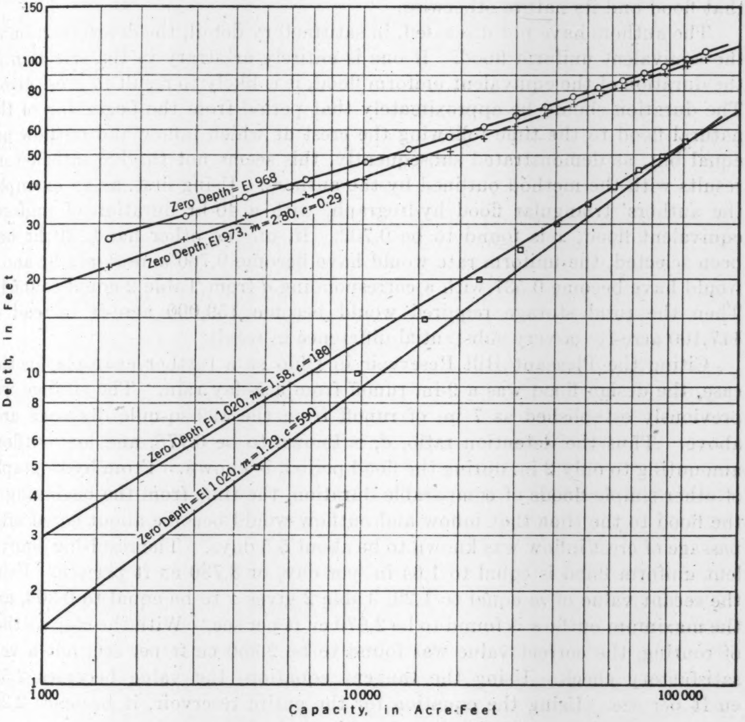

FIG. 9.—DEPTH CAPACITY CURVES; PLEASANT HILL RESERVOIR, MUSKINGUM VALLEY, OHIO

TABLE 9.—CONSTANTS IN EQUATION (1); SENECAVILLE RESERVOIR, OHIO

Elevation of zero depth	Description	CONSTANTS:	
		C	*m*
805	Natural	30	2.20
812	Sill of outlet gates	188	1.79
831	Crest of conservation weir	2,430	1.24

In Table 2, it should be noted that d varies relatively slightly within the entire range of m, as compared with the variation within the range of x. Thus factors entering into the variation of x are likely to be of greater importance that those entering into m. One of these is the value of the inflow rate of the uniform equivalent flood, which, in turn, is dependent on the duration of that flood and its nature otherwise.

The authors have not discussed, in satisfactory detail, the determination of the equivalent uniform flood. If one is entirely arbitrary in the selection of the duration of the equivalent uniform flood, it is likely to result in gross error. The duration should be approximately that period from the beginning of the natural flood to the time following the crest at which inflow and outflow are equal but, as demonstrated subsequently, this seems not to give satisfactory results with the method outlined by the authors. Using first, as an example, the authors' triangular flood hydrograph, with a 40-hr duration of uniform equivalent flood, x is found to be 0.702. If, on the other hand, 30 hr had been selected, the uniform rate would have become 9,760 acre-ft per hr and x would have become 0.537 with a corresponding d from Table 2 equal to 0.543. Then the total storage required would become 159,000 acre-ft instead of 117,100 acre-ft—a very substantial difference in result.

Citing the Pleasant Hill Reservoir in Ohio as a further example, in this case, the design flood was a 9-in. runoff from a 5-day rain. The storage was previously established as 7 in. of runoff from the 199-sq-mile drainage area above. Thus the detention ratio, d, is known to be 0.778, and low outflow, amounting to only 2 in. during the flood period, is known. From hydrographs of other simple floods of comparable duration, the time from the beginning of the flood to the time that inflow and outflow would become about equal after passage of crest inflow was known to be about 5.5 days. The resulting equivalent uniform flood is equal to 1.64 in. per day, or 8,780 cu ft per sec. Using the secant value of m equal to 1.29, Table 2 gives x to be equal to 0.303, and the maximum outflow is found to be 2,670 cu ft per sec. With the step method of routing, the correct value was found to be 2,350 cu ft per sec, not a very satisfactory check. Using the tangent equation, the value becomes 2,530 cu ft per sec. Using the equation for the entire reservoir, it becomes 2,280 cu ft per sec, the best of the three by this method.

Assuming the five-sixths rule to hold, however, one can establish the approximate maximum rate of outflow directly, knowing its volume to be 2 in. from the watershed above, over a period of 5.5 days. The average, which is five sixths of the maximum, is 1,950 cu ft per sec. The maximum, in turn, is found to be 2,340 cu ft per sec, a very good check. It should be noted that this does not require the use of any uncertain values of m or x.

The authors suggest the term "outflow ratio" for the ratio between maximum outflow rate and the inflow rate for the equivalent uniform flood, which is also designated as x. This is an excellent suggestion, but the writer would suggest that it be used also with respect to the ratio between the maximum outflow rate and the maximum inflow rate of the natural flood from which the equivalent uniform flood is derived. They are in error, however, in stating that this term designates the same value as Professor Woodward's "protection ratio." At no point has the writer been able to find that Professor Woodward gave any definition for x other than $\frac{O}{I}$.[23] "Protection ratio," as used by him without definition,[24] is a satisfactory expression, and is the peak inflow divided by the peak outflow. It is a ratio always equal to, or greater than, 1, and the reciprocal of outflow ratio if the authors will accept the writer's modification of their term "outflow ratio."

J. O. JONES,[25] ASSOC. M. AM. SOC. C. E. (by letter).—This paper is a distinct contribution to the literature on flood routing. It recognizes the fact that the storage capacity required is dependent, chiefly, upon the total volume of the flood, and only in a minor degree upon the flood distribution.

When the authors' method is applied to the problem of estimating the storage capacity required for a given maximum flood, with a given maximum outflow, a fairly large range of values of volume is obtained, depending upon the assumed duration of the equivalent uniform flood. This may be seen by applying Equation (2) and Table 2 to a concrete example.

The two floods shown in Fig. 10 have the same volume (140,000 acre-ft) but are markedly different in distribution. The exponent, m, in Equation (1) is 2.18. Hence, the values shown in Table 10 are obtained. The variation in the results may be inconsequential, in view of the more or less speculative nature of the design flood. The percentage variation in the required storage, however, is considerable. The step method as applied herein by the writer indicates that an equivalent uniform flood of 28,000 acre-ft per day with a duration of $T = 5$ days will agree exactly with design flood No. 1 but will underestimate, slightly, the required capacity for flood No. 2. Hence, it appears that a criterion is needed, which will indicate, at least approximately, the value of T in Equation (2).

TABLE 10.—DESIGN FLOOD, MARAIS DES CYGNES

Item	Description	DURATION T, IN DAYS			
		4.0	4.8	5.6	6.4
1	Equivalent uniform flood, in thousands of acre-feet	35.0	29.2	25.0	21.9
2	Outflow ratio, x	0.5	0.6	0.7	0.8
3	Detention ratio, d	0.585	0.498	0.409	0.315
4	Storage (S) required, in thousands of acre-feet	81.9	69.7	57.2	44.1
5	Maximum depth, h, in feet	43.5	40.4	36.8	32.8

It may be that a criterion can be obtained graphically. As a matter of fact, the volume of storage required is represented by the area between the flood hydrograph and the outflow hydrograph. Although the outflow curve cannot be obtained, except by the step method or its equivalent, a fair approximation may be had by considering the outflow curve to be a straight line drawn from zero to the point of maximum outflow (line *E E*, Fig. 10). The area between the straight line and the flood hydrograph overestimates the required capacity in every case. In the present example (Fig. 10) the excess is 19% for flood No. 1 and 14% for flood No. 2. An improvement may be had by noting that the outflow hydrograph is quite flat at the maximum point. By sketching a curve, which is required to pass through the points *E*, and which retains the characteristic shape of the outflow hydrograph, one may obtain a result quite close to that obtained by approved step methods.

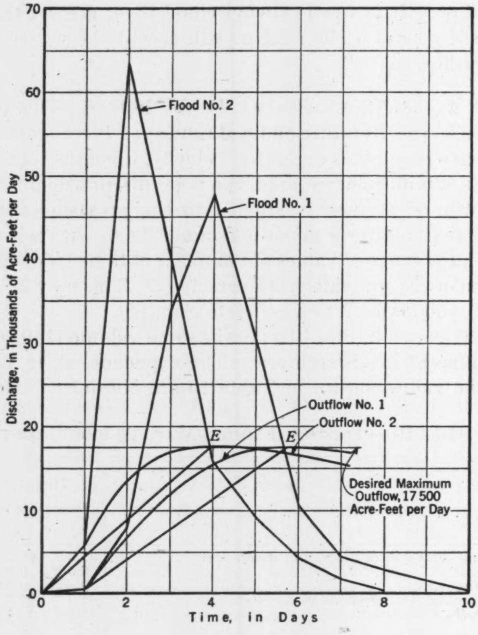

FIG. 10

W. C. HAMMATT,[26] M. AM. SOC. C. E. (by letter).—There seems to be a tendency in recent years to go into intricate and exact mathematical analyses of problems which are fundamentally of a practical nature. This tendency causes one to lose sight of, or at least to have one's vision obscured toward, the fundamental principles involved.

In the matter of the design of storage for protection against flood damage, certain factors are taken into account, any one of which may be the ruling one, depending on the facts in the particular case. These factors are as follows: (1) The expected flood flow of the stream, in intensity, duration, and frequency;

---

[26] Civ. and Cons. Engr., Los Angeles, Calif.

(2) possible storage capacity of the proposed reservoir; (3) the capacity of the stream bed below the reservoir outlet to handle flows without flood damage; and (4) the economics of the situation—that is, the comparative study of possible property damage from flood peaks, and the cost of protective storage. In spite of the methods developed in recent years, factor (1) is still an uncertain one, based on historical analysis of the watershed itself and of others with similar characteristics; and its uncertainty has been demonstrated frequently by the occurrence of floods far in excess of the predictions developed by customary methods of analysis. Factors (2) and (3) are capable of practically exact computation. Factor (4) is capable of exact analysis under existing conditions, but is subject to the uncertainty of development and values at a future date.

Beginning with factor (4), the economic study, and calculating the maximum cost that can be assumed for flood protection, considering that unlimited storage capacity can be developed, the computer works back through factors (3), a constant, and (1), an estimate, to obtain factor (2), the desired solution. It is a fundamental principle that the solution of a problem, wherein one or more of the factors are inexact, cannot itself be exact. It follows that, since factor (1) is an estimate only, the engineer can only design to meet this assumed condition, and that simplified methods of computation may be used with as much likelihood of success as more exact mathematical ones.

If the possible storage capacity is limited to less than that necessary for complete control, the problem resolves itself into a mere determination of the rectangular outflow to utilize the entire storage capacity available, always assuming that the benefits derived by this regulation are in excess of its cost. Since the total quantity, rate, and duration of the inflow are indeterminate, a graphical solution, preferably by an assumed mass curve based on historical data, is sufficiently accurate. There is nothing new in this method of treatment, the only recent development being the improved methods of flood prediction, and the writer believes that further refinement is not consistent with the uncertainty of the basic data.

C. J. Posey,[27] Assoc. M. Am. Soc. C. E., and Fu-Te I,[28] Esq. (by letter).—Some of the discussers contend that the writers' method of functional design is more complicated than the step-routing methods which give, as a result, the complete outflow hydrograph. For the problem at hand, in which only the maximum outflow and maximum storage need be found, this is decidedly not true. Given data on a reservoir site and an inflow hydrograph, a number of corresponding values of maximum outflow and maximum storage can be computed by the writers' method in less than a tenth of the time needed to determine the same number of values by the fastest step-routing methods available. The routing methods not only involve more computation, but are indirect as applied to this problem.

The accuracy of the writers' method hinges upon the validity of three steps in the solution: (1) Representation of the capacity-depth data for the reservoir site by the exponent m; (2) representation of the inflow flood hydrograph by an equivalent uniform flood hydrograph; and (3), use of the writer's values of the detention ratio in Equation (2). Each step has been questioned or criticized by one or more of the discussers. The points raised pertinent to these steps will be discussed in reverse order.

---

[27] Associate Engr., Iowa Inst. of Hydr. Research; Associate Prof. of Hydraulics and Structural Eng., State Univ. of Iowa, Iowa City, Iowa.

[28] Prof., Coll. of Eng., National Southwest United Univ., Kuenming, Yunnan, China; formerly Graduate Student, Dept. of Mechanics and Hydraulics, State Univ. of Iowa, Iowa City, Iowa.

The correctness of the tabulated values of the detention ratio, for use in Equation (2), can be verified by checking the mathematical derivation given in the Appendix. This is admittedly a somewhat lengthy procedure, but it is not at all necessary for an understanding of the method, nor even for verifying the values in Table 2. They can be verified by step-routing computations, a more lengthy and indirect method, but one that would be preferred by many. A partial check on the correctness of the tabulated values is afforded by the agreement shown, in the appropriate area of the table, with Mr. Woodward's "five-sixths rule." Professor Kampmeier points out that the agreement holds over a considerable range of values of m and x. None of the discussers who express doubt as to the correctness of the writers' method presents any evidence that the values in Table 2 are faulty.

In discussing the determination of the equivalent uniform flood, it should be remembered that the design flood itself is very uncertain. Even after the expenditure of considerable time and energy on the hydrological studies, the size and shape of the design flood cannot be guaranteed to within 20% or 30%. Precise quantitative prediction of the magnitude and frequency of floods is an art that the hydrologist has not yet mastered. Mr. Hammatt states of the expected flood flow that "its uncertainty has been demonstrated frequently by the occurrence of floods far in excess of the predictions developed by customary methods of analysis."

On most large engineering projects, the work must proceed simultaneously on several fronts. Functional design studies for the reservoir cannot be postponed until the final results of the hydrological studies are available. In the early stages, when the design flood has not been definitely determined, the writers' method of arbitrary selection of the equivalent uniform flood should give results that are sufficiently accurate for preliminary studies.

Use of the word "arbitrary" was probably ill advised. The writers assumed that a certain amount of judgment would be used in selecting the uniform flood. By use of the rules suggested by Messrs. Soucek and Kindinger for selecting the uniform flood, however, the amount of skill necessary to obtain good results is greatly reduced—so much that the method of the paper (with the following revisions) can be used for the final design, giving greater accuracy, in most cases, than the most optimistic hydrologist would claim for his design flood.

For preliminary studies, a mass curve of the inflow is plotted. A straight line approximating the mass curve for the entire flood is then drawn. The uniform flood corresponding to this straight line may be used instead of the "arbitrarily" selected uniform flood of the paper.

For final design, the mass curve of the inflow hydrograph is plotted, but the straight line approximating the mass curve is made to fit not the entire flood, but only that portion up to the time that the inflow rate equals the desired maximum outflow rate. This gives a different equivalent uniform flood for each different outflow, but the gain in accuracy is considerable, especially for the higher values of outflow. Subsequent computations with the several uniform floods are the same as for the "arbitrarily" selected flood of the paper. In contrast to the method outlined for preliminary design, this method ignores the tail of the inflow hydrograph, a procedure to increase the accuracy originally recommended by Mr. Woodward.

Messrs. Soucek and Kindinger both give rules for drawing the straight line best approximating a portion of the mass curve of inflow. The writers find little difference in the results. This phase of the problem seems worthy of further study.

Isolated cases may be encountered to which the writers' method of functional design will not apply, even if use is made of the refinements suggested by Messrs. Soucek and Kindinger. These cases can be recognized in advance. An uncertain value of m, an unusual inflow hydrograph, or a high value of x may warn of the necessity for a check by the step method. In any case, the outlet size selected as a result of the functional design studies should be checked by step-routing methods.

Professor Kampmeier and Mr. Smith both note that the value of m for a given site varies as the elevation of the zero depth changes. This does not indicate that any lack of definiteness attends the use of this exponent, but rather that the storage-depth relation for a given site changes as the zero depth is changed to correspond with the elevation of the outlet. A satisfactory straight line can be drawn through the upper portions of any of the rows of plotted points in Fig. 9. Slight differences in m are inconsequential, as Mr. Smith himself points out.

Professor Kampmeier inquires as to the zero depth used in determining the values of m for the 250 reservoir sites. Practically all of these were based on depths measured from the bottom of the reservoir. Professor Kampmeier is correct in stating that the value of m based upon a higher spillway level would be smaller. Use of the writers' values of the detention ratio for reservoirs with weir-type outlets presupposes that the reservoir is full to spillway level at the beginning of the flood, and that the outflow at the beginning of the flood is insignificant.

Professor Jones suggests an alternate method for the functional design that represents the ultimate in simplicity. The outflow hydrograph is sketched by eye upon the plot of the inflow hydrograph. Measuring the area between the two by planimeter gives the maximum storage directly. The method would be indirect in determining the maximum outflow corresponding to a given maximum storage. Compared with the writers' method, Professor Jones' method allows for greater flexibility in taking into account the actual shape of the inflow hydrograph, but it would require considerable skill to sketch the correct curves for different values of m and n—that is, for different characteristics of the reservoir site and outlet. With sufficient practice, always followed by a check by the step method, one might possibly develop the skill necessary to obtain accurate results by Professor Jones' method.

The writers are glad that the discussion brought out the special routing methods given by Messrs. Stevens, Bednarski, and Werner. Although they do not apply advantageously to the problem of the paper, they possess advantages in certain situations, and are not, to the writers' knowledge, available elsewhere. The method described by Mr. Stevens, especially, should be studied by every student of flood-routing methods.

Professor Kampmeier and Mr. Smith call attention to the writers' error in referring to Mr. Woodward's "protection ratio." Mr. Woodward defined the protection ratio to be "the proportion which the maximum flood inflow bears to the maximum outflow through the conduits," so that it is not identical with the writers' outflow ratio, and is not misleading, as the writers stated. Both terms are necessary and their use should be continued. The construction of tables similar to Table 2, embodying the protection ratio, as suggested by Professor Kampmeier, would be a difficult but possibly profitable task.

Mr. Smith questions the writers' assumption of 100% efficiency for the operation of gate-controlled outlets, apparently believing that, through modern data-gathering and forecasting methods, efficiency greater than the "100%" assumed by the writers could be reached. Although the writers will admit the theoretical possibility of greater efficiency in operation, they believe that a study of the records of the operation of reservoirs with gate-controlled outlets would show that the assumption of 100% efficiency is too high.

The writers are especially grateful to Mr. Kindinger for his important contribution in pointing out that the detention-ratio tables may be condensed and generalized by introducing $u = \frac{n}{m}$. Although it seems advisable to retain the present form of the tables for use in most cases, in which n is either $\frac{1}{2}$ or $\frac{3}{2}$, Mr. Kindinger's suggestion opens up wide fields of usefulness for the writers' method. The ogee spillways mentioned by Mr. Soucek, problems in the filling and emptying of tanks, the design of highway culverts with pondage, and many other cases, where the discharge relationship varies as some power of the head different from $\frac{1}{2}$ or $\frac{3}{2}$, can be solved advantageously by use of the writers' method and tables, with the modification suggested by Mr. Kindinger. The details of these various applications need to be developed carefully.

The writers wish to thank all of the discussers for their interest. If this paper results in an improvement in the functional design of flood control reservoirs, much will have to be credited to the discussers' efforts.

RECONSTRUCTION OF THE WALPOLE-BELLOWS FALLS ARCH BRIDGE

By H. E. Langley,[1] Esq., and Edward J. Ducey,[2] Esq.

With Discussion by Messrs. J. B. French, Lewis D. Rights, Conde B. McCullough, H. M. Nelson, and H. E. Langley and Edward J. Ducey.

Synopsis

The three-hinged, open-web, steel, arched highway bridge between the Towns of Walpole, N. H., and Bellows Falls, Vt., was one of the several crossings over the Connecticut River which were seriously damaged during the spring flood of 1936. For example, Fig. 1(*a*) shows the New Hampshire end of the span, Fig. 1(*b*), the Vermont end; and Fig. 1(*c*) is a detail view of the damage to the bottom chord. It is apparent that the lower chord sections and the adjacent web members of the up-stream truss below high-water level were so badly crippled that it was necessary to close the bridge to all vehicular traffic; and the responsible authorities were compelled to decide between major repairs to the structure and its replacement with a new one.

This bridge had been in service only since 1908, and the steelwork in general had been carefully maintained so that a considerable expenditure for repairing the damage was warranted. The consulting engineers who designed the structure[3] were called upon to submit a design for repairs. They formulated a general plan involving supports near each end, with four along the interior of the arch, all supported on timber pile groups. Detailed plans were prepared, and bids were taken for the work on this basis. The successful bid ($120 000) included all operating hazards and was somewhat in excess of the anticipated costs. The danger element involved in this undertaking was relatively high because a further accident to the main span might not only result in the loss of the structure but would probably involve difficulties at the Bellows Falls power plant, situated immediately below the bridge, which is a main link in the electric power system that serves this region. In studying the situation the Bridge Division of the New Hampshire State Highway Department decided that it was more feasible for the State to assume the risks incident to this extra-

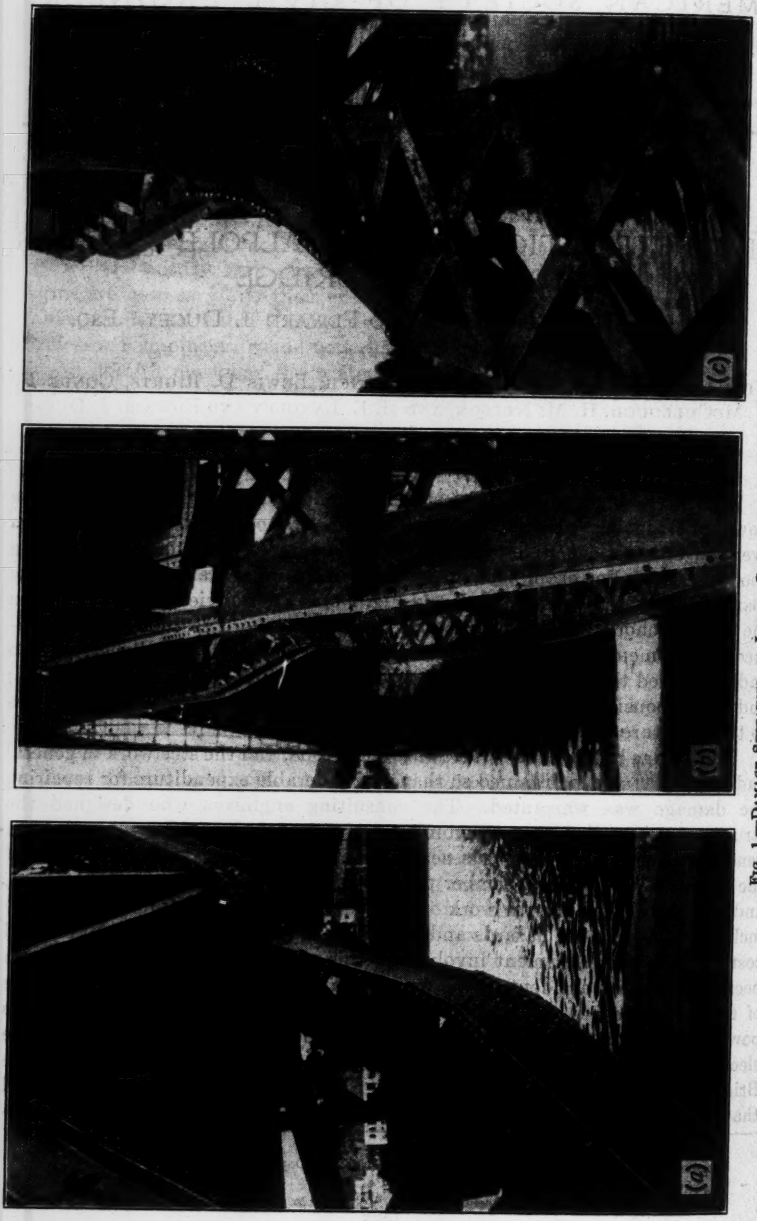

FIG. 1.—DAMAGE SUSTAINED BY LOWER CHORD AND ADJACENT MEMBERS

hazardous procedure than the contractor. To do this it was necessary to let the fabrication and erection contract on a "cost-plus" basis to a competent structural steel contractor who would co-operate with the State forces in driving the piles and placing the concrete.

In consultation with the contractor's engineers a study was made to eliminate some of the more hazardous features of the undertaking by keeping the river as clear of falsework as the condition of the structure would admit. Accordingly, a plan was devised incorporating the use of temporary cable ties (see Fig. 3) to take the horizontal thrust of the arch, thus converting the span temporarily into a tied three-hinged arch to be carried on falsework towers near the original supports. With the falsework at the ends of the span it could not only be protected, if necessary, from floating ice by means of ice breakers or fenders extending out from the river banks, but it could be constructed from the shores as well.

The use of temporary cable ties and other features introduced in this work seem somewhat unusual, and it is believed that a description of the procedure followed will be of interest to engineers and contractors generally.

INTRODUCTION

The original structure consisted of two ribs in each truss—a top chord and a bottom chord—each being a parabola of the same general dimensions, spaced one above the other 14 ft apart vertically. The top chord consisted of two 15-in. channels with a cover plate 24 in. wide and laced at the bottom flanges. The bottom chord consisted of two similar channels laced top and bottom, with additional side plates making the gross area approximately equal to that of the top chord. The diagonal members were made up of two 5 in. by $3\frac{1}{2}$ in. by $\frac{3}{8}$ in. angles, generally, single laced. This construction is shown quite clearly in Fig. 2. Since the two ribs are parabolas of the same dimensions, the thrust line under uniform load would be midway between them because the spring-line pins and the pin at the crown were placed midway between the two. The ribs in each truss were drawn together in the last two panels at either end of the span to meet at the spring-line pins so that the thrust from the two main arch trusses was carried by the skew-back shoes to the concrete abutments which were supported principally on wooden piles. The floor system, which was hung from the trusses with loop-rod hangers, had a system of lateral or wind bracing, which had for the chords of the system two members in the planes of the two main trusses. These extended throughout the length of the span, and were connected to the bottom chords of the main trusses by slotted connections to provide expansion due to temperature changes. Although these members were comparatively light, being made up of two 6-in. by 4-in. by $\frac{1}{2}$-in. angles, together with the diagonal bracing in the top-chord lateral system, they played an important part in saving the structure from collapse when the up-stream truss was damaged.

A very interesting and complete description of the construction of this bridge, together with discussions covering the erection of this and similar structures, was presented by Lewis D. Rights, M. Am. Soc. C. E., on April, 1, 1908.[3]

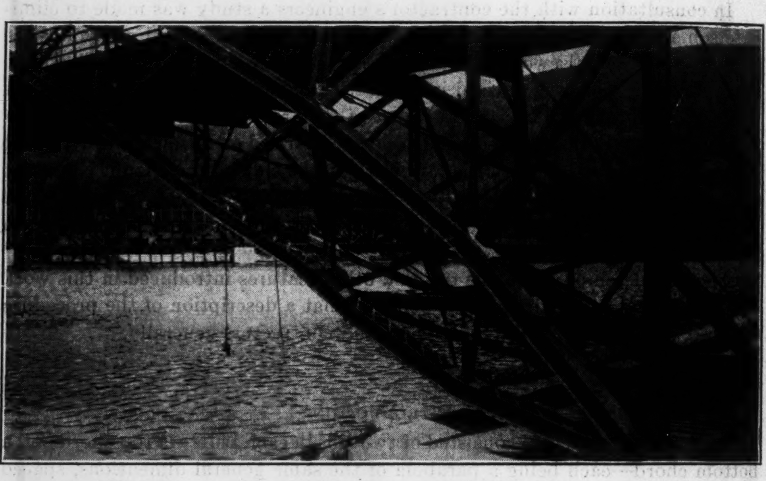

FIG. 2.—VIEW OF DAMAGED MEMBERS AT THE VERMONT END OF THE SPAN

THE PROBLEM

At the time the structure was built the low-water level was several feet below the present pool elevation, but improvements in the power development facilities on the Connecticut River have raised the normal pool to its present level (Elevation 115.5) a foot or so above the original spring-line pins. The depth of water now varies from about 19 ft at the abutments to about 50 ft at mid-channel. Borings taken at the abutments and at the temporary tower sites indicated about 20 ft of mud, sand, and boulders which gradually consolidated into a series of alternate strata of hard sand and gravel at a depth of about 35 ft, underlaid with solid rock at about 60 ft to 70 ft below the riverbed. The high water during the flood of 1936, which caused the damage to the main span, reached Elevation 125.5 (see Fig. 3) and covered the roadway at the New Hampshire end of the span.

The direct damage was caused by the ice jam which collected back of the main arch and extended entirely across the river. The impact and the sustained pressure from this ice so disabled the up-stream truss that the lower chord ceased to function as originally designed, and the greater part of its share of the load was distributed to the top chord. The diagonals $U_2 L_3$ and $U_3 L_4$ and the vertical $U_3 L_3$ (Fig. 3) assumed part of the thrust from the lower chord and distributed it to the top chord, while the ties which formed the chords of the lateral bracing in the floor took up the greater part of the remainder. Although the crippled chord sections undoubtedly carried some stress, it was

FIG. 3.—ADOPTED PLAN OF FALSEWORK FOR ALTERATIONS AND REPAIRS

largely of a secondary nature, rather than direct thrust, serving mainly to prevent the top chord from buckling upward under the thrust from the diagonals. There was a particularly noticeable tendency for the top chord to yield directly over the damaged bottom-chord sections. This was overcome effectively at the New Hampshire end by the use of ballast, the State Highway Department having placed about 50 tons of sand and gravel on the floor at this point immediately after the accident to the span. At the Vermont end 12 in. by 12 in. timber shores were wedged between the end shoe of the approach span and the haunches of the arch so as to load the haunches.

Evidently, the top chord of the up-stream truss was partly relieved of the load distributed to it from the lower chord, by the action of the top-chord lateral system which, apparently, transferred part of the load across to the down-stream truss that was not directly damaged by the ice jam. The diagonals that appeared to take the thrust from the lower rib of the up-stream truss were manifestly in serious danger of buckling under direct stress, because there was a very evident bow or lateral deflection in several of these members that disappeared after the span was picked up on the falsework, and the condition of stress in the web members throughout the structure was decidedly uncertain.

A careful survey made soon after the flood subsided revealed that the damaged up-stream truss had dropped about 6 in. at the crown and raised about 2 in. at the haunches. The crippled section of chord at the New Hampshire end shortened about 1¾ in. and the corresponding chord section at the Vermont end shortened about 3 in. Although the affected chords were battered down stream under the impact of the ice, the entire span was found to have moved up stream so that, at the temporary tower on the New Hampshire end, it was necessary to move it back down stream 2½ in., and at the Vermont tower it was required to move it back 4¾ in. to align the structure with the original skewbacks after removing the damaged ends of the trusses. The shoes were not disturbed, of course, so that this displacement was caused by a side lurch of the structure, which was quite noticeable when viewed endwise along the bridge. The span leaned up stream, being about 1 ft out of plumb at the crown. Emergency repairs included the timber bracing, shown in Figs. 2 and 4, framed and wedged into the plane of the lower chord to prevent further side lurch.

In considering the repairs to be made to the structure it was imperative that some provision should be made to prevent a recurrence of the damage. Manifestly the lower chords of the span were quite exposed to the impact of floating ice, and it was obvious that the damaged steelwork would have to be replaced. It was observed that by removing the three panels of truss at each end, and by replacing the old members with the arrangement shown in Fig. 3, the new steel below high-water level could be encased in heavily armored reinforced concrete. This would not only protect the steel but it would also provide somewhat more lateral clearance for the floating ice at high-water level. It would thus provide a less vulnerable structure and, incidently, it would maintain the same type of structure with a 54 ft shorter span. In this arrangement the main thrust under uniform load is carried, by a single member, from the new pin set on the original thrust line to the original skew-back. The effect of partial loading is taken care of through the cantilever action of the new steel below the pin, which steel is supported by a group of four steel piles under each truss, at a new shoe set approximately 20 ft forward of the skew-back shoes.

The obvious uncertainty of stress throughout the structure, and the general instability of the span, injected a hazard into the problem which became an important factor in the procedure to be followed in making the repairs. Little could be done toward making preliminary repairs, other than the emergency repairs already described, to secure the structure sufficiently to carry erection loads. It was impossible, therefore, to construct temporary falsework by working from the span, and it was impractical to reach the site with floating equipment because of the location and the proximity of the power company's dam situated in the river immediately below the span. Therefore, in addition to keeping the river as free from falsework as possible, the plan of procedure which seemed most feasible was the one involving the least number of temporary towers and so devised that they could be erected by working out from the shores on temporary bents, keeping entirely free of the damaged span so as to disturb it as little as possible.

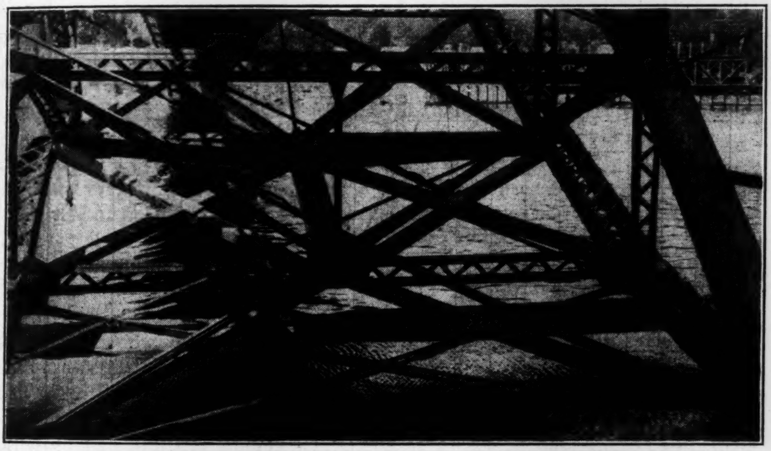

FIG. 4.—EMERGENCY BRACING IN THE PLANE OF THE BOTTOM CHORD; VIEW FACING ALONG THE BRIDGE TOWARD NEW HAMPSHIRE

THE PLAN ADOPTED

The plan decided upon was to pick up the span on temporary wooden pile towers placed as close to the shores as the steel to be removed would permit, and to take the thrust by means of temporary ties, and then remove the damaged ends and replace the old steel with new material after the structure had been leveled up and re-aligned on the temporary towers.

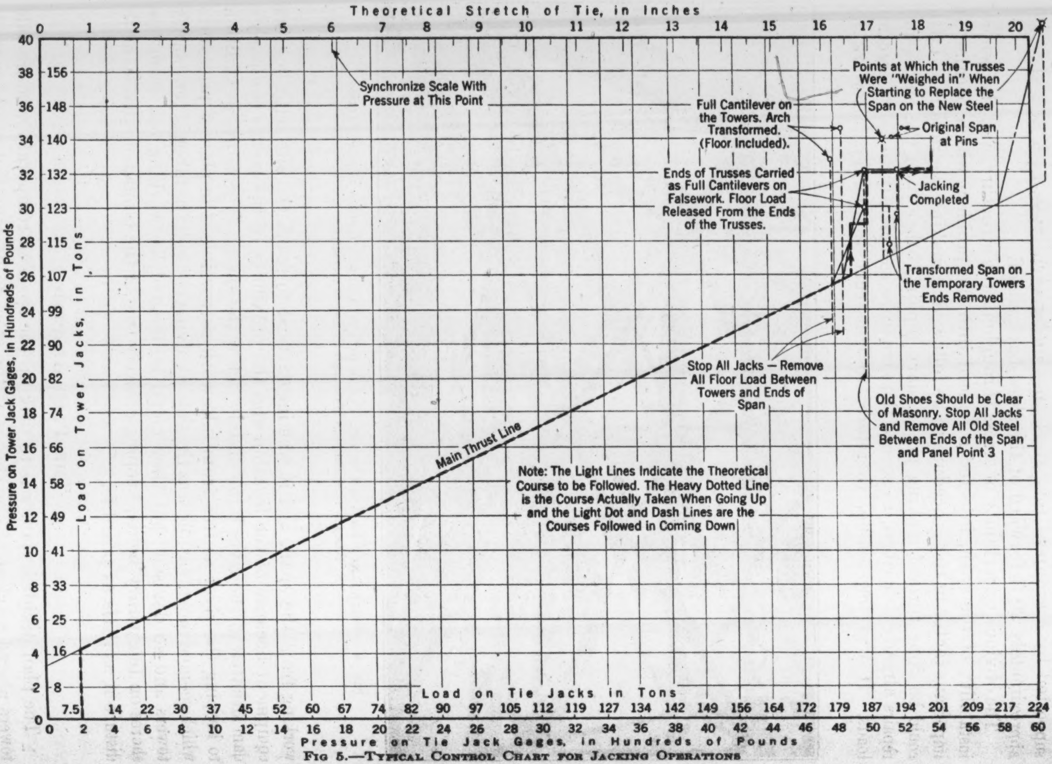

FIG 5.—TYPICAL CONTROL CHART FOR JACKING OPERATIONS

Handling the structure in this manner required that the ties be designed to take a thrust of 195 tons for each truss, with an allowance for an over-load estimated at 20%, and that each tower be designed to carry a vertical load of 143 tons at each truss. The total weight of the span was 572 tons before removing the old steel. These loads varied somewhat during the process of reconstruction as the removal of old steel and the addition of new members, removal of the floor system, etc., altered the weight of the span with a corresponding variation of the stress in the ties. This is shown in Fig. 5, with an over-load of 18% due to snow and ice, and the shifting of the old pavement (which was torn up and piled along the up-stream truss during the progress of the work).

The difficulty of taking these reactions on the trusses at points where such severe concentrations were not provided for in the original design presented somewhat of a problem, especially because provision had to be made for jacking devices to take up the stretch in the cable ties, and any temporary members used would have to be inserted without disturbing the structure, or without impairing the strength of the members carrying stress. This was accomplished by inserting a system of temporary members in the trusses at each tower, as shown in Fig. 6. A tower member, *A O C D*, was used to carry the vertical reactions and to intersect with the thrust member *O B*, on the thrust line, at Point *O*. The tie stress was then introduced at Point *O* by placing the jacking devices back of this point so that the line of action of the tie would pass through Point *O*.

During the jacking operations the stresses were introduced into the tie and the tower member by picking the proper increment of stress in each so as to keep the resultant stress coincident with Line *O B* as nearly as possible and tangent to the thrust line at this point. The stress from the thrust member was taken up at Point *B* by two distributing members, *B A* and *B C*, and delivered to the upper and lower chords at Points *A* and *C*. As shown in Fig. 3 a brace was used to steady the base of the tower member at the New Hampshire end but this was so arranged that it served no other purpose.

All of the new steel was completely fabricated in the shop. The temporary members were designed so that they could be erected by parts without impairing the strength of the members in the structure to which they were to be connected, except for the removal of a pair of lacing bars in each plane of lacing on the top and bottom chords. Field connections were drilled in the old members, either to a template or to match the new steel blocked in place on the falsework. Main connections were fully riveted and secondary connections and braces were bolted.

For each tie a pair of $2\frac{1}{2}$-in. galvanized bridge cables (6 by 19 on a 7 by 7 core, pre-stretched) were used to straddle each truss and were supported throughout the span on 2 in. by 6 in. wooden cross arms bolted to alternate hangers. These cables had an ultimate strength of 305 tons each and were pre-stretched to 120 tons, approximately 20% greater than the calculated working load. The modulus of elasticity of these cables after pre-stretching was 19 600 000 lb per sq in., for loads of less than 130 tons. Because of their relatively light weight in proportion to their strength, their flexibility, the ease with

The tension in each tie was equalized between the two cables by means of a short balance beam to which the cables were attached at one end of each truss, and the system was stabilized by means of a beam extending across the roadway from one truss to the other. The other end of all cables was attached at this beam. These beams (also referred to as jacking beams) were all free to rotate about a vertical axis, on the center line of each truss, by resting on seats in the jacking devices, provided with knife-edge bearings. This system permitted the independent movement of the trusses so that one could be moved longitudinally, or one tie length could be varied without affecting the other when supporting the temporary towers. The jacking devices being in compression, it was necessary that they be stabilized by means of some kind of bracing system. This was provided as shown in Fig. 7, using diagonal braces composed of rods fitted with turnbuckles and clevises so that the rods could be let out or taken up as might be required to rack the bracing.

Because of the limited clearance for the jacking beams used to equalize and stabilize the cables, it was necessary to provide two jacking devices, one at either end of each tie so that the tie could be taken up or let out at either end. However, both jacking devices were not to be used simultaneously. One 300-ton jack with a 9-in. run-out was used in each jacking device, and shims were provided for fleeting the jacks as well as for carrying the load independently when the jacks were not actually in operation. Fig. 8 shows the detail of the jacking device and, with Fig. 9, shows the assembly of the jack beams and the method of attaching the cables to the beams. Both cables were pulled into place at once, with the falls attached to socket baskets, a bail being welded on them. The falls were set 3 ft 8 in. apart so that the socket baskets would clear the jacking device. When the cables were pulled into

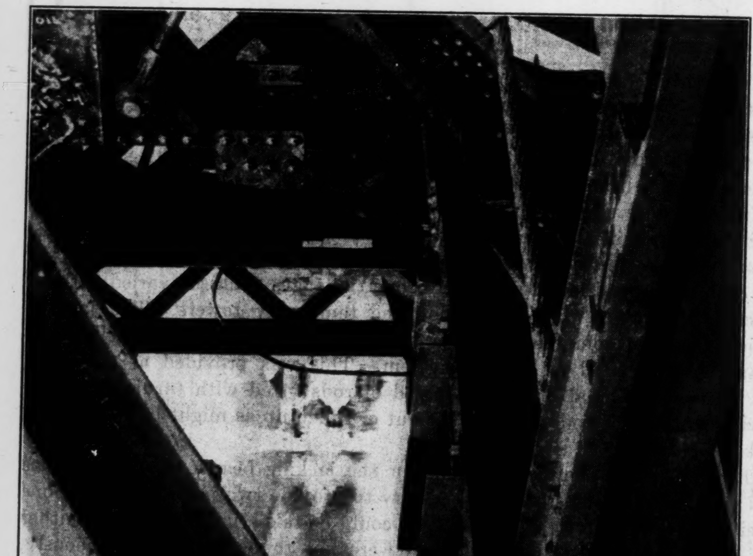

FIG. 9.—DETAIL VIEW OF THE JACKING DEVICE AND THE ANCHORAGE OF THE CABLES TO THE STABILIZING BEAM

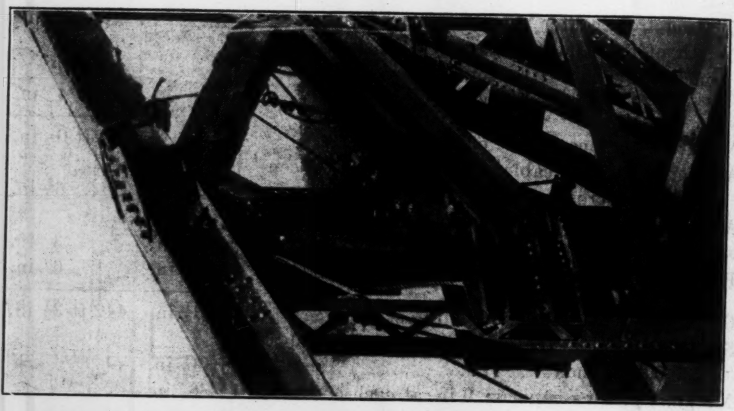

FIG. 10.—VIEW OF DISTRIBUTING MEMBERS, WITH THE JACKING DEVICE REMOVED TO SHOW THE JACK SEAT STIFFENERS

position, they were drawn together to a spacing of 2 ft 11 in. and the remaining beams were assembled in place. Fig. 10 shows the jacking device removed to give a view of the stiffeners and stiffener plates on which the base slab supporting the jacks was seated.

The arrangement of the jacks and shims on the towers is shown in Fig. 6. Four 100-ton hydraulic jacks, also having a 9-in. run-out, were used on each tower, two under each truss. A built-up box girder was provided to carry the load from the jacks to the tower member (see *A O C D* in Fig. 6). The tower member was framed through the girder and was fitted with a base slab to rest on a set of shims when the jacks were not in operation. To provide for movement of the span on the towers these shims were carried on a double nest of rollers so that movement could be obtained both longitudinally and laterally. Longitudinal movement was governed by the jacks in the main ties and lateral movement was controlled by a system of "steamboat" ratchets, shown as a part of the bracing in the plane of the tower in Fig. 6. All diagonal bracing in the towers, except that in which the ratchets were used, was composed of rods with turnbuckles and clevises for adjustment when aligning the span.

Each of the temporary wooden towers was composed of two bents of twelve piles each. The position of all piles, particularly those in the bents forming the approach for the traveler from the shore, had to be located very carefully to avoid interference with the old steel and the emergency bracing, or with the new members. The main towers were braced rigidly and the services of a diver were required to place the bracing below water level. All piles, including the steel piles used in the permanent construction, were driven with a double-acting steam hammer (No. 9-B-2), in swinging leads handled from the boom of the traveler, the operator working out from the shore on the temporary bents. These bents also served to support the old floor system at times during the progress of the work. The old floor system over the new work was not removed completely until the span was almost fully transformed into a tied arch and carried on the temporary towers. The purpose of this procedure was to avoid disturbance to the structure, or any changes in the condition of loading, until the span was well under control.

Jacking operations on major bridge structures are quite common but they are normally conducted under circumstances such that the conditions of stress in the structure are known, and they may be kept under control throughout the procedure. In the case of the jacking operations, in transforming this arch span, the engineers and erectors were confronted with the problem of beginning to operate jacks on a structure in which the stresses were mostly unknown and with many of the members manifestly over-stressed. A jacking load applied in the wrong position or in the wrong direction, or the successive applications of the loads in the wrong order, might easily have caused a failure in some over-stressed member.

The general layout of the jacking equipment is shown in Fig. 11. All pipe, tubing and fittings were $\frac{1}{2}$-in. double, extra-strong stock. All pumps, gages, and central control valves were placed in a group on the floor of the bridge and connected to the jacks at different elevations, by copper tubing.

Emergency stop-and-release valves were placed in the lines, at the jacks. The tie jacks and the tower jacks in pairs, were placed on separate pipe lines and each line was connected so as to operate normally from a separate hand pump. However, the hook-up was so arranged that both pumps might be "cut in" on either line by means of the stop-and-release valves; but, as the two lines worked under different pressures, they could not operate together.

Fig. 11.—Layout of Hydraulic Jacking System

Separate hydraulic gages were used on each line to control the pressure in the jacks; 5 000-lb gages were used with the tower jacks, and 10 000-lb gages in combination with 2 000-lb gages (for low pressures) were used with the tie jacks. Mercury gages (10 000-lb pressure capacity) were connected into the system at either end of the span for use as master gages in the event any discrepancies appeared in the readings of the hydraulic gages. However, it was not necessary to use the master gages because the others had been adjusted and calibrated at the tool house before they were shipped to the field, and they worked perfectly in every way. Their sensitiveness was very apparent on the gages governing the stress in the ties where the slightest variation in pressure on the jacks, as indicated by the gages, was instantly discernible on the yardsticks clamped in the jacking devices to measure the stretch in the ties. All pumps and gages at either end of the span were placed in a group on the floor of the bridge. There was no hydraulic connection between the jacking system at one end of the span and that at the other; but a telephone system fitted with headsets was provided as a means of co-ordinating the work. A foreman was placed in charge of the jacking equipment at each end; and, with the gages arranged so that he could read the jack pressure at a glance, he applied the pressure as directed by the engineer in charge, or the superintendent, who directed the operations by working from jacking charts prepared in advance (see Fig. 5).

Two jacking charts were required, one for each end of the span. Differences in the weight localized over the towers—such as the temporary steel, removal of part of the floor system, sand ballast, etc.—necessitated somewhat greater working pressure in the tower jacks under the New Hampshire end. Fig. 5 is the chart for the Vermont end only; the other, although different, was essentially the same so far as this description is concerned.

In starting to transfer the weight of the span to the falsework, the temporary steel (which weighed approximately 26 tons and which had been carried on the falsework by shimming up tight under the foot of the temporary tower members shown as $A\ O\ C\ D$ in Fig. 6) was first to be picked up on the tower jacks at 350 lb pressure. The initial stress on the ties (5 tons on each cable) corresponded to a gage pressure of 260 lb on the tie jacks. Actually the initial tie stress was less than 5 tons per cable and the load on the tie jacks was picked up at 200 lb pressure. According to the jacking chart this initial pressure on the tie jacks called for a total pressure on the tower jacks of 410 lb. The first step then, having taken the tie load on the jacks at one end, was to raise the pressure in the tower jacks to 410 lb at both ends of the span, working simultaneously. Both trusses were jacked in unison from the start, with the corresponding jacks in each truss "cut in" on the same line. This first step placed the entire jacking system "on the chart." Thence using the tie stress to govern the tower reactions in accordance with the chart, the tie stress was stepped up by 200-lb increments of pressure alternating with the tower jacks and stepping up the latter simultaneously at all points. Thus, with the tie jacks at 200 lb and the tower jacks at 410 lb the ties were stepped up to 400 lb while the tower jacks "stood by." The towers were then stepped up to 505 lb while the tie jacks "stood by." This process was repeated until a pressure of 2 600 lb was obtained on the tie jacks, corresponding to a tension of 97 tons in each tie with a total stretch of $8\frac{3}{4}$ in. on the cables. To keep the stretch in the ties about equally divided between the two ends of the span the jacking operations on the ties were then switched to the other end of the structure and the process was continued as before until a pressure of 4 780 lb on the tie jacks was obtained. This pressure corresponded to a stress of 178 tons on each tie, or 89 tons on each cable. This was the limit of the jacking that should be done, according to the calculated reactions, by following the direction of the thrust line on the chart, because it was the maximum stress obtainable in the tie with the structure resting on the towers and with the ends cantilevered under full floor load. During the jacking to this stage the sand and gravel ballast that was placed over the haunches of the up-stream truss, at the New Hampshire end, was gradually removed and the nuts were removed from the old anchor bolts in the skew-backs.

In this stage the increment of pressure on the towers jacks was approximately 95 lb, which corresponded to an increase of load of 4 tons on the tower. In effect this amounted to a concentration of 4 tons on each truss at each of the towers. It was thought that the most seriously over-stressed members in the structure, before any jacking was done, were the diagonals, U_2-L_3 and U_3-L_4, and the verticals U_2-L_3 (see Fig. 3). These diagonals were in compression and the verticals were in tension. To jack upward on the tower member (that is, to apply the increment of the tower reaction before the increment of tie stress was applied) would operate to increase the stress in these members; but, applying the tie-stress increment first, and then applying the tower-load increment, would serve to reduce these stresses. Therefore, this was the procedure adopted.

When the stress of 180 tons on the tie was obtained, all jacking was stopped and the floor deck removed; part of the steel work in the floor system was left supported on the temporary pile bents, but all floor load was removed from the first three panels at each end of the span. The approach span at the Vermont end was also supported on falsework at the east end to permit the removal of the old shoes a short time later.

Referring to the jacking chart in Fig. 5, it will be observed that there are two positions plotted for the positions of the jack pressures after departing from the main thrust line: One is for the maximum, and the other is for the minimum, calculated dead weight of the span. When jacking was resumed after the floor loads were relieved, the tie jacks were "stepped up" by increments of 100 lb of pressure, each being followed by a "step-up" of the tower jacks by an increment of 300 lb of pressure. After one "step-up" on the tie and one "step-up" on the towers the tie stress was determined as at 4 980 lb per sq in. jack pressure, a total of 185 tons. At this tie stress the chart indicates that the old shoes should be clear of the masonry skew-backs. An inspection of the shoes failed to indicate that this was so, and the tie jacks were once more stepped slowly to a jack pressure of 5 000 lb per sq in. The tower jacks were then "stepped up" slowly and when the pressure in these jacks reached 3 200 lb per sq in., an observer stationed at the down-stream shoe, at the New Hampshire end, reported that there was a very definite crack in the ice and grout around that shoe but no change could be observed at the other shoes. The ties were then stepped up to 5 200-lb jack pressure and it was observed that the joint U_3 on the up-stream truss (New Hampshire end) had opened about $\frac{1}{16}$-in. This joint, as well as all others at which the new steel was to be connected to the old, had been prepared previously for dismantling by replacing the rivets with bolts. The down-stream jacks all around were then cut off the lines and the up-stream truss was stepped up to 5 400 lb per sq in. (201 tons), on the tie, and to 3 300 lb per sq in. (136 tons), on the tower, and then returned to the previous position corresponding to the down-stream truss. This was simply a test movement. Movements at the joints that were bolted indicated that the members were carrying no stress of any importance, and consequently the stress in the trusses between the jacking devices and the ends of the span was released. The total stretch in the ties at this point was observed to be 17$\frac{5}{8}$ in.; and the total rise in the span directly over each tower, as determined by taking elevations on the floor beams at these points, was found to be $\frac{7}{8}$ in. The span was landed on shims in this position and the jacks released. The nuts were placed back on the anchor bolts at the Vermont end so as to stabilize the structure on the falsework and the old steel was completely removed from the New Hampshire end.

The total jacking time required for this work was about 12 hr including the time required for testing the jacking system for leaks, etc., and for checking the gages, one against the others. During the first stage of the jacking, which increased the tie stress to 178 tons, the weather conditions were very inclement. This stage of the work was begun at 8:00 A.M. on November 10, 1936. The day was quite cold, the temperature being approximately 32° F, and soon after the work was started it began to rain, and continued to rain and sleet until noon. After noon a high wind rose and continued for the remainder of the day. This made progress with the jacking very slow so that by evening the first stage of it was only about half completed. Work was continued the following morning; the weather was clear and the temperature was approximately 20° F, but it was much more favorable than the day before. The remainder of the jacking necessary to bring the tie stress up to 180 tons was completed in about 2$\frac{1}{2}$ hr. After about a day required to remove the floor load from the ends of the span the jacking was completed in approximately 1.5 hr. Under favorable weather conditions the entire jacking operations would have been completed in about 7 hr of actual jacking time.

After the removal of the old steel at the New Hampshire end, the jacks on the temporary tower at the same end were raised about 15 in., rotating the span vertically about the old pins at the Vermont end and, of course, raising the jacks at the Vermont tower proportionately. The tie jacks at the New Hampshire end of the span were also "taken up" (that is, the ties were shortened) about 5 in. on the up-stream truss and about 3 in. on the down-stream truss. The tower jacks on the up-stream truss, New Hampshire end, were then lowered about 2 in. and the bracing rods in the tower were adjusted at the same time by means of the turnbuckles. The difference of 2 in. in the distance that the ties were shortened relative to each other removed most of the sag in the up-stream truss and almost straightened the span vertically, bringing it back almost plumb. The actual pressures on the jacks during this set of operations naturally did not change except that, in the case of the tie jacks, the tie stresses increased about 10 tons to overcome the roller friction. The New Hampshire end was free and it was simply moved to make clearance for the erection of the new steel. At this time also the span was moved down stream 2.5 in. on the New Hampshire tower and almost 4.5 in. on the Vermont tower by means of the steamboat ratchets shown in the lower stage of bracing in Fig. 6. This jacking, together with the adjustment of various turnbuckles in the temporary rod bracing, was done simultaneously with the jacking to "take up" on the ties. Otherwise it is doubtful whether the span could have been moved so far laterally on the Vermont tower.

STEEL ERECTION

Before removing the old steel the spring-line pins were referenced carefully and the center line of the structure was established on the towers to correspond to the skew-backs. There was a rumor locally that, during high water in 1927, a wash-out had occurred back of the New Hampshire abutment, causing it to settle. Careful measurements were made to determine the relative positions of the pins all around, and levels were taken to check their elevations. It was found that the old pins were within $\frac{1}{16}$ in. of the same elevation. The nominal span was 540 ft, center to center of the old pins, but the measurements taken indicated the up-stream truss pins to be 540.05 ft and the down-stream pins to be 539.91 ft, center to center—a difference of $1\frac{3}{4}$ in. The measurements also showed that this difference was divided between the two abutments—$\frac{1}{2}$ in. to the New Hampshire abutment and $1\frac{1}{4}$ in. to the Vermont abutment. This finding seemed to indicate that each abutment had rotated about a vertical axis causing a change of span for both trusses. The up-stream truss was lengthened $\frac{5}{8}$ in. in span and the down-stream truss was shortened $1\frac{1}{8}$ in. This seemed rather improbable since there were no cracks in the wing walls nor any other visible indications of settlement; and, since the New Hampshire abutment (which was supposed to have been the one affected) had the least skew, no further attention was paid to the settlement rumor. However, the new steel was set to "square up" with the center line of the structure by working from the referenced position of the old pins in the down-stream truss to establish the length of the reconstructed span according to it. The up-stream truss span was shortened $1\frac{3}{4}$ in. in this manner.

Before placing the new main members the light-welded steel trusses shown in Fig. 12 were shored and blocked in place to serve as guides to hold the steel piles in exact position while driving. These trusses were designed for this purpose as well as to serve as reinforcement for the concrete piers. The weight of the piers was assumed to be carried by the piles entirely, without any other support, although the rip-rap, on which the piers were placed and through which the piles were driven, was washed off and cleaned of mud, etc., by a diver using a fire hose. The timber crib shown in Section *A–A*, Fig. 12, had been filled with rock and capped with concrete some time after the original span was completed. The rip-rap apron around the old crib was cleared away where necessary and 12 in. by 12 in. timbers were cut away to make room for the new steel piles. The piles were driven to a penetration of about 65 ft to rock and were capped with steel grillages to support the forward shoes of the new steel work. The shoes were set in position carefully on the grillages, to measurements from the referenced position of the old pins. The wood sheet-piling was then driven to provide forms, and the concrete placed by means of a tremie. Anchor bolts 3.5 in. in diameter, two for each shoe, were placed in the shoes and the concrete was poured to the bottom of the grillages. The posisions of the shoes were checked, the nuts on the anchor bolts locked down tight,

FIG. 12.—CONSTRUCTION LAYOUT OF THE VERMONT PIER

the steel below the new pins erected, leveled up and shimmed in place, and the skew-back shoes which were fabricated on the main thrust member were grouted in position. The old anchor bolts were left in the skew-backs and were used to provide anchorage for the new steel. The new members were then riveted up completely and the concrete was poured to the floor level in the concrete encasement shown in Fig. 12. The calculated loading on these steel pile groups which consisted of four, 12 in. W F, 55 lb sections was:

Load per pile:	With wind	Without wind
Before placing concrete	+ 4 to − 47	− 5 to − 38
After all concrete was placed	− 67	− 58

The new steel above the pin was erected independently of that below, in cantilever fashion, by connecting at the old splices on both the top and bottom chords which were placed conveniently just above Joints U3 and L3 (see Fig. 3). This is shown in Fig. 13.

After the steel at the New Hampshire end of the span was erected, the tower jacks were released to lower the New Hampshire end by rotating about the Vermont pin; and the tie jacks were "let out," to make the pin holes in the new steel match. The pins were then driven and the old steel at the Vermont end was cut away immediately and removed. The span was then raised about 15 in. at the Vermont tower by rotating about the New Hampshire pin and the cables taken up again to make clearance for the new erection as had been done at the opposite end of the span. To complete the straightening-up process, the span was moved down-stream approximately $\frac{1}{2}$ in. farther at the Vermont tower, the up-stream truss was dropped about 2 in. at this point, and the tower bracing adjusted.

The same procedure was followed in the erection of the steel, and in the other construction at this end of the structure, as was used at the other end. When the erection was completed and ready to be connected, the loads at all towers and the stresses on the ties were picked up on the jacks and "weighed in," one truss at a time. The jack pressures were then plotted on the charts (see Fig. 5). The up-stream tie jacks picked up the stress on the tie at 6 100 lb per sq in. (228 tons); the up-stream tower jacks picked up the load at 4 100 lb per sq in. (168 tons); the tie jacks in the down-stream truss picked up at 5 100 lb per sq in. (190 tons); and, the tower jacks under this truss picked up at 3 400 lb per sq in. (140 tons). Due to the fact that several inches of snow and ice covered the deck of the span at this time and during the previous month, the old asphalt plank flooring had been piled along the up-stream truss, permitting the old plank sub-floor to become thoroughly soaked with water. The pressures at which the jacks picked up the loads were considerably higher than those required to raise the span at the beginning.

After the loads were weighed in on the jacks, the span was lowered, rotating about the New Hampshire pin, and the ties were released slowly so as to bring the pin holes into position for driving. The jack pressures did not change during this operation so that as the pins were driven the pressures in the jacks were already charted.

As soon as the pins were driven the structure was lowered immediately and landed on the abutments. Since the up-stream truss was the heavier of the two, it was started down ahead of the other and the pressures in the jacks controlling it were lowered to meet those of the jacks controlling the down-stream truss. The corresponding jacks on the two trusses were then thrown in on the same lines and the two trusses were thence brought down in unison. Thus, the down-stream jacks were "cut off" the lines but were held under pressure, and the tower jacks at both ends of the up-stream truss were lowered simultaneously by opening up a release valve in the line while the tie-jack line was kept closed and the pressure was permitted to "drift" as the tower jacks released the pressure. These jacks were not turned loose but were held under control by "stepping down" at 200-lb increments.

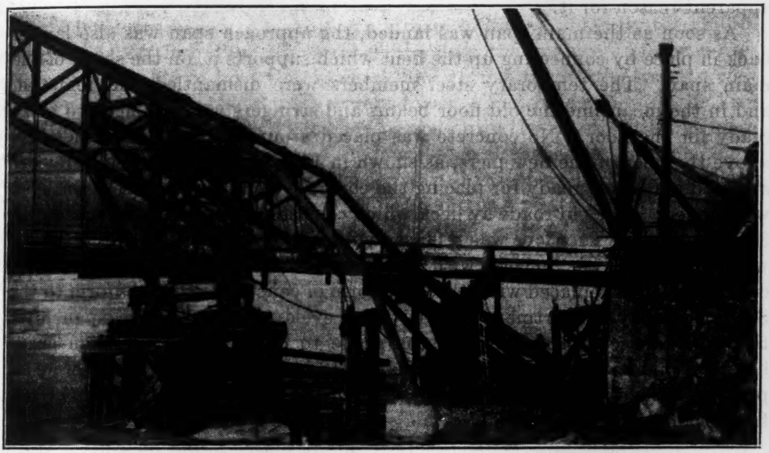

Fig. 13.—New Steel Erected at the New Hampshire End of the Span Ready for Driving the Pins

As the jacks were stepped down the ties gave up the load very leisurely, accumulating sag between the supporting cross arms until the original initial stress in the tie was reached. The shims were placed under Tower Members *A O C D* (Fig. 6) to take the local concentration of temporary members away from the trusses, and the release valves in all jacking lines were thrown wide open. The total time required to release the jacks and land the span was a little less than 2 hr.

Throughout the jacking operations in raising the span on to the towers, and again when landing it on the abutments, a peculiar difference between the action of the tower jacks at the two ends was manifest. As the stress in the tie was "stepped up" along the thrust line, the tower jack pressure at the end of the span, where the tie jacks were in operation, had to be pumped to the full increment of pressure, whereas the tower jack pressure at the opposite end drifted automatically in exact accordance with the charts, with little or no pumping after the falsework in the towers had taken up the initial settlement.

At first this was thought to be the result of excessive settlement in the tower where the jacking was required; but after switching the jacking procedure to the opposite end of the ties this same peculiar action continued as before: The jacks on the tower, which had been drifting as stress was jacked into the tie, now had to be jacked the full increment, and the others, which had previously required the full increment of jacking, now drifted with the tie stress. The same perplexing phenomenon continued when landing the span, with no very apparent reason for it.

As soon as the main span was landed, the approach span was also landed back in place by connecting up the bent which supports it, on the shoes of the main span. The temporary steel members were dismantled and removed, and in the meantime the old floor beams and stringers were replaced to make ready for the floor. No concrete was placed around the new steel members above the floor of the new piers, as shown in Fig. 12, but the forms were constructed and made ready for placing the concrete encasing as soon as the span was landed. The old roadway deck which consisted of asphalt plank laid on a 3-in. wood plank sub-floor was replaced with a 3-in. concrete floor and the old wooden sidewalk was replaced with 2-in. floor. The old railing, which consisted of gas pipe, was replaced with a modern form of construction to conform to the State Highway Department standards. Levels taken over the span after the work was completed showed the grade to conform to a uniform curve having a middle ordinate of approximately 18 in. and the floor beams were all practically level, the maximum difference in the elevation of the ends of any floor beam being only $\frac{3}{8}$ in.

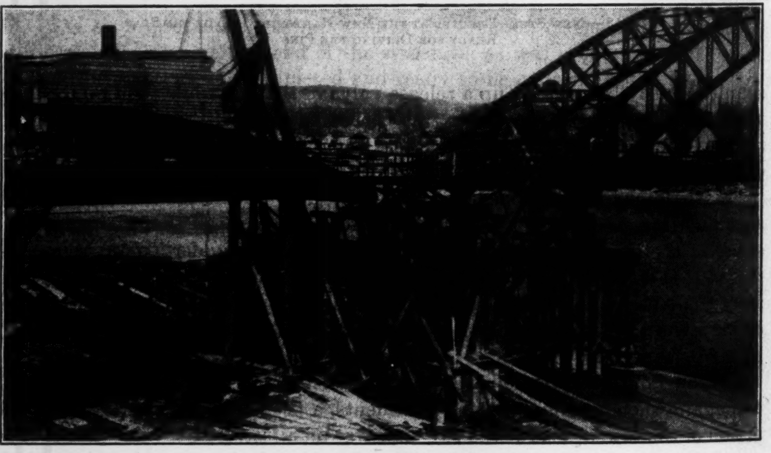

Fig. 14.—Falsework at the Vermont End

Working Conditions

The weather conditions at the time this work was in progress were very erratic and generally unfavorable. The late fall and winter seasons began quite cold and before the first of December the river was frozen over with ice approximately 10 in. thick. About this time it became necessary to lower the pool level to reach the old steel around the skew-backs. This broke the ice along the shores but it caused no serious trouble and the ice quickly sealed up as the cold weather continued. About December 9, with several inches of snow in the Connecticut River basin, the temperature rose suddenly and in three days the precipitation was reported variously as 3 in. to 4 in. Under the effects of this rise in temperature and the rain, the ice broke loose on the river above the pool level and began to move down stream quite rapidly. By the skillful manipulation of the rolling lift gates in the dam the engineers of the power company were able to hold this in check and permit the State forces to construct an ice fender to shield the Vermont tower. Fig. 14 is a view of the Vermont end immediately after the ice had passed down the river. It broke loose about 300 ft above the bridge, and the lower edge of the ice can be seen below the bottom chord of the truss. The ice is still intact around the falsework due to the protection of the fender. Since there was no fender to protect the New Hampshire tower, the gates were kept closed at that end of the dam, to hold the ice and to throw the current to the main channel on the opposite side, discharging the ice past the tower which was protected by the fender. This was so successful that it was decided that it would not be necessary to build a fender to protect the New Hampshire tower.

CONCLUSION

This project is somewhat novel in the history of arch-bridge construction, as was the design and erection of the original span.[3] The magnitude of this undertaking was by no means measured by the quantity of new material involved; nor was it measured by the cost of the project. The cost of a new structure is scarcely a criterion of the amount of the work incident to the planning and careful procedure which was necessary, and although the final cost was approximately three times the original cost of the superstructure, a new span would have cost several times the amount of the repairs and, in addition, the cost and hazard of removing the old structure would have to be taken into consideration. Because of the depth of the pool at this point and possible damage to adjacent property, the removal of the old span as it stood at the beginning of repair operations would have been quite a problem and undoubtedly would have cost at least half as much as the proposed repairs.

The load capacity of the span is adequate for the location. The arch trusses were found to have capacity for the H-15 loading and the floor system, including the slightly greater weight of the new concrete-steel deck, has a capacity 20% greater than the H-10 loading—that is, the H-12 loading, applied in accordance with the American Association of State Highway Officials Specifications. Therefore, no special alterations were necessary to raise the structure to the traffic requirements. However, when designing the new deck and hand-rail, the roadway was widened from 20 ft to 21.25 ft, and the width of the sidewalk was established at 4 ft 10 in. The new steel and foundations were designed for the H-15 loading, and since the steel in the main trusses is in such excellent condition that it will probably last indefinitely if properly maintained, it is possible, if future traffic demands it, to revise the entire structure to the H-15 loading at relatively little cost.

On the basis of replacement costs the State Highway Department, by repairing the damaged span, provided an adequate structure to meet the traffic requirements at approximately one-third the cost of removing the old structure and replacing it with a new one of the same capacity. By the use of the specific method adopted to do the work enough was saved to provide for the new deck and hand-rail.

As compared to the original structure, having a span of 540 ft with the spring-line pins 14 ft below present high water, the reconstructed arch has a span of 486 ft with the spring-line pins 3 ft above high water, assuring ample protection against a repetition of the damage at the same high-water level.

This work was done by the engineering and erection forces of the American Bridge Company, who furnished and fabricated the steel, and who furnished the erection equipment, in co-operation with the engineers of the Bridge Division of the New Hampshire Highway Department and their construction forces.

Although all operations were made difficult throughout the work by weather conditions, ice, high water, and extreme cold weather the progress and the final results were very satisfactory to the State Authorities and the bridge is adequate in every way for modern traffic.

DISCUSSION

J. B. French,[4] M. Am. Soc. C. E. (by letter).—The work described in this paper shows boldness and resourcefulness in planning and much skill and constant alertness in the supervision of its execution. It does not appear that any traffic, either vehicular or pedestrian, had to be maintained at any stage of the work, and therefore the risk of loss of life was confined to the workmen engaged. Nevertheless, it is obvious that any mistake, either in planning or in execution, might easily have wrecked the damaged structure, with the loss of the lives of the workmen and serious property damage. While the work was in progress, it undoubtedly appeared spectacular to those who stopped to give it intelligent attention, but after it was finished the spectacular quality necessarily disappeared and left no monumental features to attract attention. In fact, the best evidence that the work described has been completed effectively will be the failure of present observers to discover that any repairs or "reconstruction" had ever taken place.

Work of this kind, like foundations and structural frames hidden from view by subsequent construction, and all falsework and temporary structures for purely erection purposes constitute a most important part of engineering construction; detailed descriptions of such work, such as are given in this paper, are always valuable contributions to the publications of the Society.

It seems to the writer, however, that the value of the paper would be enhanced if a more detailed statement of the actual cost of the various parts of the work, as executed, could be included. In the "Synopsis," the authors state that "the successful bid" on the "design for repairs" submitted by the "consulting engineers who designed the structure" was $120 000; and under the heading "Conclusion" several general statements are made as to costs, but no clear statement is made of the cost in detail of doing the work as described.

Lewis D. Rights,[5] M. Am. Soc. C. E. (by letter).—The original bridge between Bellows Falls, Vt., and Walpole, N. H.—a 540-ft arch span across the Connecticut River, built in 1904—was an ambitious project years ahead of its time. When it was planned, the Advisory Engineer, the late J. P. Snow, M. Am. Soc. C. E., and the Consulting Engineer, J. R. Worcester, Hon. M. Am. Soc. C. E., both recognized the advantage of keeping the structure above possible ice damage; but the Bridge Committee, composed of local business men from both sides of the river, would not hear to the extra expense.

In 1906, a year after the bridge was finished, a flood damaged the bottom lateral bracing at one end and the consulting engineer recommended that a reinforced concrete slab be installed to brace the lower chord and protect the lower laterals, but there was no authority at hand to see that this was done.

In 1928, the dam was raised, making the pool 10 or 12 ft higher; the canal was enlarged and the power-house expanded. It was inevitable that sooner or later this elevation of the dam would cause a destructive flood.

---

[4] Cons. Engr., Jamaica, N. Y.

[5] Roselle, N. J.

At this time some strong State agency could have bargained with the power company to provide the necessary protection around the abutments as a partial offset for the benefit of increased power production. As is usually the case, the local authorities were incapable of handling these matters against a large power corporation, especially as the bridge was an interstate project. Had these precautions been taken, the heavy expense indicated in the paper might have been avoided. Fortunately, the entire bridge was not lost and the State of New Hampshire was able to take charge and repair it.

Offhand it would seem that the cheapest method of supporting the bridge during repairs would have been to use falsework towers as was done originally. So far as the writer knows the conditions were the same as when the bridge was first erected, except that the water was deeper in the pool. This would mean longer, and possibly a few more, piles but it would have been balanced by shorter timbers in the framing of the towers.

If the work had been done after the spring rise, when the ice was gone and before freezing weather, there would have been very little risk, even if a summer flood had occurred. Assuming that the erection cost of the bridge originally was one-half the cost of the superstructure, or $20 000, and taking into account the new repair material, it is difficult to understand the lump-sum bid of $120 000. On the "cost plus" plan the State assumed the risk from operating hazards, and if this had been done for the lump-sum plan this bid would probably have been much cheaper. Allowing for the changes in the abutments it would still leave a difference of $50 000 to $75 000 to be explained.

The writer hopes that the authors will give the costs of the repairs in detail; that is, the abutments, new repair steel, erection including cables and the new floor as well as information as to what was covered in the lump-sum bid.

All this does not in the least detract from the high praise due the engineers for the skill whereby the span was shortened from 540 ft to 486 ft and the spring-line pins raised 17 ft. The success of their scheme is the result of bold design, careful planning, and constant care.

The original bridge was erected in upper New England, over a capricious river, in the depth of winter because of the delays of the Committee in awarding the contract. The bridge was repaired, also, in the winter months, probably due to the delays of the "powers above" in reaching decisions. It is to the glory of engineers that they are willing to accept difficult and hazardous conditions forced by circumstances beyond their control, without wasting time quibbling about them, and that they then proceed to overcome these hazards successfully.

CONDE B. McCULLOUGH,[6] M. AM. SOC. C. E. (by letter).—Congratulations are due the authors, not only on a most coherent presentation, but also on an exacting piece of reconstruction, efficiently and safely performed. As aptly emphasized in their report, jacking operations on major structures are normally conducted under conditions of rigid stress control, whereas in this case the distribution of stress at the beginning of jacking operations was highly problematical. The care which they exercised in controlling both the magnitude and the position of the applied thrust leaves little to be desired.

---

[6] Asst. State Highway Engr., State Highway Dept., Salem, Ore.

It is gratifying indeed to see a "repair job" of this character accorded the distinction of a detailed technical write-up. In general, repair work has earned few plaudits, notwithstanding the fact that its technique often calls for design and erection procedures more complicated and involved than in new construction. Moreover, marked economies are generally effected; and in the present instance, the expenditure of approximately $120,000 operated to save the cost of a new structure which the authors point out would have amounted to several times this sum. Economies such as this are all too frequently lost sight of in the enthusiasm for new construction.

An instance which occurred many years ago involving the Morrison Street Bridge in the City of Portland, Ore., illustrates the economies which are sometimes possible. This structure consisted of a 384-ft draw-span flanked on one end by a 205-ft fixed truss span and on the other by two spans at 267 ft. In 1919 this structure had apparently been outgrown by its traffic, and was in a rather unfortunate condition of disrepair. The floor system was inadequate, the eye-bar chains over the draw-span towers were seriously overstressed, as were most of the compression members in the bottom chord with the span open, and popular opinion had it that the bridge was outmoded, inadequate, and unsafe. After a rather complete investigation, the writer recommended a system of repairs estimated to cost $208,000, based upon the following economic comparisons:

(*a*)	Estimated cost of repairs	$ 208,000
(*b*)	Estimated total maintenance expense for ensuing 12-yr period	111,000
(*c*)	Total cost during ensuing 12-yr period for repairs, renewals, replacements, and ordinary maintenance (Item (*a*) + Item (*b*))	$ 319,000
(*d*)	Annual interest charge on capital to reconstruct ($2,500,000 at 5%)	125,000
(*e*)	Total interest expense for 12-yr period	1,500,000
(*f*)	Financial saving realized by repairing old structure (Item (*e*) − Item (*c*))	$1,181,000

This report was finally adopted, the repairs made at a cost of slightly more than $200,000 and the structure is still carrying unlimited and unrestricted traffic after an extended service period of nearly twenty years. This instance is typical of many wherein distinct economies accrue from the maintenance of old construction even if the repair work involved is complicated and somewhat hazardous.

In connection with the adopted jacking procedure, the authors mention the extreme sensitiveness of the system, the slightest variation in pressure on the jacks being instantly discernible in the device for measuring cable stretch. They also mention a rather peculiar difference between the action of the tower jacks at the two ends, involving an automatic drifting of the far jacks with little or no pumping. These two qualities—extreme sensitiveness and an inclination toward erratic behavior—seem to be somewhat characteristic of all hydraulic jacking setups.

In 1931 and 1932, the writer had the opportunity of experimenting with an hydraulic jacking system in connection with the decentering of the highway bridge over the Rogue River in Oregon. This structure consists of a group of seven 230-ft reinforced concrete arch spans, and the decentering was performed in accordance with the Freyssinet method, by means of an hydraulic system, consisting of a battery of four 275-ton jacks installed at the crown of each rib. During decentering operations, observations were made of: (1) Total jack thrusts and moments; (2) crown openings at extrados and intrados; (3) vertical movements at crown, spring line, and intermediate points; (4) internal strains at extrados and intrados at five sections in each span; (5) rotation of rib axis at crown, quarter points, skewbacks, and piers; (6) horizontal movements at spring line; and (7) temperature and shrinkage.

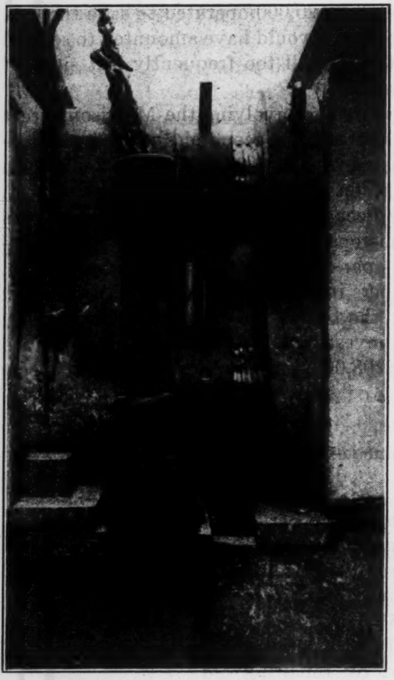

FIG. 15

Jack pressures were measured by calibrated gages, crown openings with a sliding scale and vernier, vertical movements by means of a system of water levels, horizontal movements by weighted invar wires, and internal strains by an installation of electric telemeters. The hydraulic jacks which were manufactured especially for this job by the manufacturer, who had previously designed and constructed similar equipment for M. Freyssinet, are shown in Fig. 15.

A graph (Fig. 16) shows the relation between crown thrusts as measured by the jacks, and the horizontal crown spread. It will be noted that as the jack thrust was increased the rate of crown spread increased gradually to Position 4. This increase in rate was due to the fact that, as more and more of the load was taken by the arch, the reaction of the centering against the ribs became correspondingly less, with the result that the frictional resistance to rib shortening was decreased. In Position 4, the safety rings were tightened, and the arch was allowed to stand overnight on the jacks, during which period the crown gap closed 0.03 in. due to a tightening up of the safety rings. When the decentering thrust was again applied, an additional crown spread of 0.1 in. was observed without increase in thrust. A shortening of 0.02 in. can be accounted for by the intervening drop in temperature; and the residue represented restrained shrinkage in the concrete taken up as the arch was lifted clear of its centers.

This graph, typical of a large number of similar ones for the various spans, indicates the marked sensitiveness of the system, very slight temperature and shrinkage effects being readily detectable on the pressure gages.

Another interesting phenomenon is indicated in Fig. 17 which contains graphs of crown thrust *versus* crown spread for Spans 6 and 7. It will be noted that whenever the direction of motion was reversed, a change in thrust of about 70 000 lb was necessary to reverse the motion. This rather puzzling condition persisted throughout the entire range of these experiments, and was closely checked by the telemeter readings as well. It was thought at first that jack friction might account for it, at least partly; however, a careful calibration of the jacks indicated no frictional resistance within the limits of accuracy of the gages. The only other logical explanation offered was that the joints and articulations in the spandrel structure, although theoretically free to move, possessed a distinct and fairly constant resistance to reversing motion.

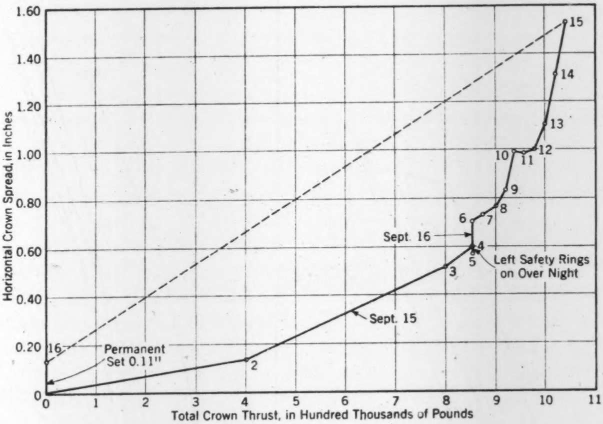

FIG. 16.—SPAN NO. 1; FIRST RUN, SEPTEMBER 15 AND 16 (CENTERS STILL IN PLACE)

The writer was reminded of this rather perplexing action when he noted the authors' description of the drifting of the distant tower jacks during the adjustment of the Walpole-Bellows Falls structure. Contradictory and confusing phenomena are not infrequent in hydraulic adjustment setups of this character.

All in all, this paper constitutes a timely and valuable contribution to the literature. More attention should be paid to the scientific design and execution of repair work. Furthermore, it would appear that there is a greater field of utility for hydraulic jacking adjustments than is evidenced by present usage. The "weighing in" of reactions on draw-spans and on continuous trusses and girders not only has the advantage of greater accuracy but also operates to eliminate any stresses that may be thrown into the superstructure through elastic support displacements or a plastic "take-up" in the foundations. For extensive installations of this kind it would appear that there are four independent methods for stress determination which may be used as a mutual check. These are: (1) Strain measurements by means of a system of extensometers, telemeters, or other suitable device; (2) deflection measurements, including angular rotation measurements at joints and at critical sections of the structure under adjustment; (3) measurement of reaction displacements at the jacks; and (4) gage readings on the jack-pressure lines.

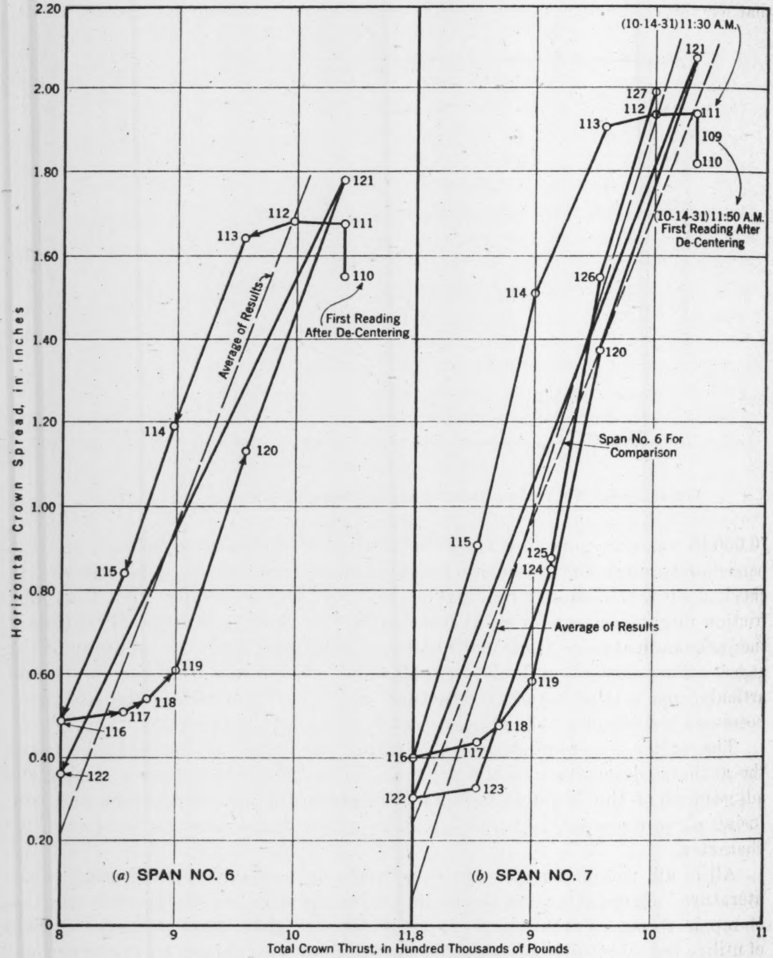

FIG. 17.—SECOND RUN, OCTOBER 14 (CENTERS REMOVED)

The paper will undoubtedly serve a most useful purpose in stimulating interest in this somewhat complicated phase of construction endeavor.

H. M. NELSON,[7] ASSOC. M. AM. SOC. C. E. (by letter).—An ice jam in the Connecticut River, composed of very large, thick cakes, which had been stalled for about four days at a point 6 miles above the Walpole-Bellows Falls steel arch bridge, passed through the bridge in the afternoon and evening of March 17, 1936. As the surface of the water and ice at that time was only slightly above the concrete protection which was placed in front of the skewbacks and extended beyond the first panel points, when the dam just below the bridge was raised some years ago, the bridge steel suffered no damage during the passage of the heavy ice jam. After the passage of the ice jam the river continued to rise, and, at about 1:00 a.m. on the morning of March 19, a crash at the bridge was heard. It is probable that the damage to the New Hampshire end of the bridge occurred at that time and that it was caused by a large ice floe. Because it was dark there were no eyewitnesses. The water was then at about Elevation 121.6.

During the early forenoon of March 19, when the Connecticut River was at Elevation 124.6, and near the peak of its flood, a floe, composed of ice that had been thrown out on a meadow during the run of the ice jam (or that had floated out of some bay that had not broken up when the ice jam came through), was seen approaching the bridge rapidly. The river bends sharply to the left in the vicinity of the bridge, and the floe was carried to the Vermont side in such a manner that the blunt front end of it struck the lower chord of the upstream arch near the second panel point. This floe appeared to have an area of a quarter of an acre or more. Just previous to the breakup, the river ice had been found to be 18 to 24 in. thick. Assuming it to be an average of 21 in. thick, the floe must have had a weight in excess of 500 tons. The velocity of the river above the bridge was about 4 miles per hr. The impact caused the entire structure to vibrate so violently that the writer, who was leaning over the bridge sidewalk railing to observe, was thrown to the floor. When the ice floe swung around toward the center of the river and passed along, it could be seen that the lower chord had a sharp offset about equal to its width. The actual damage to the New Hampshire end of the bridge was not discovered until the next day when the flood waters had receded somewhat.

The decision to reject the first plan of repair which contemplated placing a large number of pile bent supports in the river channel was a wise one, as was proved later when, in January, the ice in the river broke up over a distance of nearly 12 miles and came to rest only about 2 miles above the bridge. At this time the bridge was supported on the temporary pile bents driven at the edges of the river and protected by up-stream braced pile bents and sheeting to form a shear structure, according to the revised plan.

The authors have written a very clear and complete description of an ingeniously designed bridge-repair project completed under difficult river and weather conditions.

---

[7] Hydr. Engr., New England Power Service Co., Boston, Mass.

H. E. LANGLEY,[8] ESQ., AND EDWARD J. DUCEY,[9] ESQ. (by letter).—The writers are gratified to find that their paper was of some interest to the engineering profession, and they wish to thank the several members for their discussions. They have gained considerable satisfaction from these discussions, particularly the one submitted by Mr. McCullough, which are indicative of the careful reading that the paper received. Mr. Nelson's authoritative description of the flood and the ice floes, together with the effects on the structure, is invaluable. The January thaw to which he refers was of short duration. Had it continued for a somewhat longer period, the temporary protective works, the temporary ice fender, etc., undoubtedly would have been subjected to a severe test. Therefore, as he points out, their cost and construction were quite justified.

As revealed by Mr. French's discussion, the writers did not state that pedestrian traffic was maintained over this bridge throughout the entire progress of the work, and they did not stress sufficiently the seriousness of the property damage that would have resulted from the loss of the structure. The damage to the Power Company's plant would have been so serious if this span were dropped in the river that the safety of the structure during repair operations was the supreme consideration in planning the procedure.

The writers propose to close the discussion of their paper by considering, in connection with several features referred to in previous discussions, the costs of the various parts of the work, together with some of the more important reasons for adopting the scheme used in making the repairs.

It is interesting to note that the lateral bracing of the original structure was damaged by flood conditions the year after the bridge was completed. At that time steps were taken to provide a reinforced-concrete slab in the planes of the lower chord members from L_0 to L_2 to reinforce these members; and the necessary forms were constructed but the concrete was never placed.[10] As stated by Mr. Rights, the raising of the pool level in 1928 some 10 to 12 ft should have been contingent upon the proper protection of the abutments. The writers are not in a position to state why neither was done. The State Highway engineers recognized the hazard to which the structure was subjected and had studied several schemes for protecting it. Lack of funds, however, prevented the consummation of any of these schemes prior to the flood of 1936.

Mr. Rights states that had it been possible to proceed with the reconstruction during the summer months, falsework in the river would not have been subjected to unusual risks. Granting that this might be true, it was impossible, unfortunately, to do so for several reasons. The flood occurred in the spring, and there were several other important bridges over the Connecticut River, and other rivers as well, which were destroyed. It is obvious that some time was required to survey the damage on all of these bridges, estimate the probable cost of replacements, prepare designs, and determine on the proper sequence of construction. Except for pedestrian traffic, the reconstruction of this crossing was not so urgent as was most of the others, since there was a modern concrete arch bridge over the river a short distance below. It seemed advisable, therefore, to make only such temporary repairs as would insure the stability of the structure for pedestrians only until proper repairs could be made, and in the meantime, replace, as rapidly as possible, the structures that had been destroyed at other crossings.

[8] Designing Engr., Bridge Div., New Hampshire Highway Dept., Concord, N. H.

[9] Designing Engr., Am. Bridge Co., Pittsburgh, Pa.

[10] *Transactions*, Am. Soc. C. E., Vol. XLI, December, 1908, p. 264.

In some cases the State Highway engineers found it necessary to construct temporary bridges in order to maintain traffic with as little interruption as possible. To prevent loss of material in these temporary structures it was desirable to complete the construction of the new bridges at these locations prior to the high waters of the following spring. Although every effort was made to complete the program along these lines, two temporary bridges over the Connecticut River were lost a few weeks before the new bridges were ready for traffic.

The survey of the damage to this arch span and the plans for the reconstruction were made by J. R. Worcester, Hon. M. Am. Soc. C. E., and his associates, who were consulting engineers. Although these plans were furnished to the State within a reasonable time, and bids were called for shortly after the plans were received, it was not until the last of June, 1936, that bids were obtained. Obviously, then, unless the work could have been completed in about five months, which did not seem altogether probable, it would have been extended into the winter months, or otherwise delayed entirely until the following spring. The condition of the bridge was such that it seemed very unwise to let it stand through another winter, subject to floods and ice action, and the plan proposed by the consulting engineers seemed too vulnerable to the same elements to be undertaken at the time of year when the evident uncertainties involved in the work were so likely to cause delays. It was because of these considerations that the scheme finally adopted was proposed rather than because of economy alone. Even if it had been possible to proceed with the work during summer months, however, the writers are of the opinion that the scheme adopted would have been somewhat more economical.

The scheme originally proposed for doing the work called for the erection of six temporary wooden towers to support the arch trusses during the removal of the damaged ends and the reconstruction of the abutments. These towers were arranged in a general way very similar to the original falsework used to erect the span in 1904.[11] They varied in height from about 25 ft above normal water level at the ends of the span to about 80 ft near the middle. They were to be carried on piles, forming the lower stages below normal water level, some of which were to be driven on a batter to provide lateral rigidity.

For the construction of these towers 85 000 fbm of framed timber, about 15 tons of miscellaneous steel beams, and 144 wooden piles, 45 to 60 ft long, would have been needed. Long timber piles in this section of the country are difficult to obtain locally and are relatively expensive if imported from other sections. The fact that it was not considered safe to work from the bridge deck to construct this falsework (because of the damaged condition of the structure) would have necessitated some means, such as auxiliary falsework or the construction of floating equipment, to move the erection rig, pile driving outfit, etc., from tower site to tower site. The river at this location is not navigable, so that floating equipment, if used, would have to be brought in by overland transportation and assembled at the site. Furthermore, any such equipment would necessarily have been quite elaborate to meet the requirements on the work. Auxiliary falsework not only would have been expensive but would have filled the channel completely with this kind of timber construction. The original falsework used in the erection of the bridge was constructed by the use of "Chicago Booms," each tower being erected from the previous one, and the steel was erected by the same booms in a similar manner. Obviously, this method would not be practicable for erecting falsework with the structure already in place because of the interference with the operation of the booms, especially where long piles were to be driven on a batter. Altogether, this scheme seemed to the contractor's engineers to be a more expensive and hazardous procedure than the scheme adopted, which included in the material required for its construction 18 000 fbm of framed timber; 27 tons of steel beams; 63 tons of fabricated steel temporary members; 4 bridge cables; and the driving of 56 wooden piles, 45 ft long—all of which could be erected by working off the shore with comparatively simple erection equipment.

---

[11] *Transactions*, Am. Soc. C. E., Vol. XLI, December, 1908, p. 253.

In this procedure the amount of field work was considerably reduced by increasing the amount of material to be fabricated in the shops while the field work was progressing. This method, furthermore, provided an open channel with a minimum of falsework so placed that it could be protected by the construction of ice fenders extending out from the river banks.

TABLE 1.—COST DISTRIBUTION

Item No.	Description	False-work (1)	Removing and replacing steel (2)	Abut-ments (3)	Railing and deck (4)	Total (5)
1	Engineering and engineering superintendence	$ 900.00	$ 1 209.26	$ 1 100.00	$ 128.03	$ 3 327.39
2	Designing and drawings	808.00	305.92	832.82	....	1 946.74
3	Structural steel (shopwork only)	5 001.62	2 241.98	200.00	....	7 443.60
	Materials and Freight:					
4	Structural steel	3 762.38	2 695.87	2 323.00	....	14 651.25
5	Cables	3 770.00	....	....	....	
6	Falsework timber	2 100.00	....	....	....	
	Erection:					
7	Labor	3 930.00	13 726.48	4 984.90	5 122.80	27 764.18
8	Plant and equipment	1 179.00	4 117.94	1 495.50	1 182.18	7 974.62
9	Insurance (prorated)	3 084.19	3 443.30	1 276.76	818.57	8 622.82
10	Overhead	778.94	1 214.25	387.51	232.29	2 612.99
11	Profit	2 215.85	3 504.77	1 201.05	512.28	7 433.95
12	Subtotal, project on cost-plus basis	27 529.98	32 459.77	13 801.54	7 996.15	81 787.44
	Work Not Covered by Cost-Plus Agreement:					
13	Abutments	....	....	26 293.07	....	26 293.07
14	New I-beam deck and railing	....	....	....	15 930.12	15 930.12
15	Temporary ice fender	7 364.63	....	....	....	7 364.63
16	Subtotal	7 364.63	....	26 293.07	15 930.12	49 587.82
17	Total	$34 894.61	$32 459.77	$40 094.61	$23 926.27	$131 375.26

The actual cost of the project and the distribution of the costs to the different subdivisions of the work are shown in Table 1. From this table it will be noted that the cost of the falsework amounted to $27 529.98. This included all labor and materials required to lift the span from the abutments and make it ready for the removal of the parts to be replaced with new steel members, as well as the labor necessary to remove the same falsework material at the end of the job.

The contractor's estimate of the cost of the equivalent falsework required to accomplish the same purpose, working in accordance with the original plans for repairs, was $72 000, which did not include any allowance for contingencies. The difference between this estimated cost and $27 529.98, the actual cost of falsework as shown by Table 1, represents a saving in favor of the scheme adopted because the bid submitted by the contractor was tendered on a competitive basis and happened to be the only bid received, although plans and specifications were taken out by several contractors.

Adding the amount of the contractor's estimate for the falsework to the total of Column (2), Table 1, work common to both plans of procedure, makes a total of $104 459.77, which would represent the cost for the work on the basis of the original plan, exclusive of any allowance for contingencies or hazards. This amount deducted from $120 000, the amount of the original bid, leaves $15 540.23, approximately 15% to cover these items. The actual direct expenditure for contingencies is represented by the item of $7 364.63 for the cost of the ice fender. Had a second ice fender been found necessary for the protection of the New Hampshire end of the project, the total expenditure for contingencies would have been very close to the contractor's estimate allowance.

The original bid covered only the items listed in Columns (1) and (2); the State was to construct the necessary reinforced-concrete additions to the existing abutments for the protection of the steel. The decision to renew the railing and deck was made at a later date and the assignment of part of the work of reconstructing the abutments to the contractor was incorporated in the cost-plus agreement at the time it was decided to handle the project on this basis.

The reconstruction of the abutments proved to be the most difficult and time-consuming part of the work due largely to the difficulties encountered in driving the piles. Although the original plan was altered by the substitution of 8 steel H-piles for 42 wooden piles at each abutment (which facilitated the driving through the rip-rap), interference with old timber cribbing necessitated the employment of a diver to assist with the work. Had the original plan been followed the writers are convinced by the experience with the foundations and abutments that the falsework would have been destroyed and the structure would have been lost because the work, according to the revised plan, was progressing when the January flood occurred and had been delayed only about six weeks because of the revision of the plans.

In Table 1, Items 4, 5, and 6 include the cost at the bridge site of the steel bearing piles, reinforcing cages, temporary and also permanent fabricated steel, plain beams, and cables. Items 7 and 8 include the driving of the steel bearing piles, erecting all steel in the foundation and superstructure, all falsework labor, removing old steel and falsework, removal of old timber deck and railing, and painting new steel. Item 13 includes the placing and removal of the cofferdams, the placing of concrete and all reinforcing steel not included in Items 4 through 8, and the furnishing and placing of stone rip-rap around the abutments.

Reference to the tabulated costs indicates that the work covered by the original bid of $120 000 was accomplished for approximately $67 350, due to changes in the method of procedure. This in no way reflects on the original plans prepared by the consulting engineers. They were well conceived and prepared; they served excellently as a basis for the invitation for bids and for the designation of the work to be accomplished. The job was essentially a steel-bridge erection project, and on such work the choice of methods is always best left to the erectors. Governed by available equipment, personnel, and other factors, no two contractors are likely to choose the same procedure, and the success of the project often depends upon ability to recognize opportunities and the skilful change in plans to take advantage of them.

WIND BRACING IN STEEL BUILDINGS

FINAL REPORT OF SUB-COMMITTEE NO. 31 COMMITTEE ON STEEL OF THE STRUCTURAL DIVISION

Introduction

After a period of activity extending over ten years, during which it has issued six Progress Reports, some of them of considerable length, the Sub-Committee submits its Final Report. It is impracticable and unnecessary, of course, to restate in detail all the facts elicited during the investigation. The more important aspects of these and the conclusions and recommendations made, however, are summarized in what follows, under the general headings of (*A*) Prescribed Wind Force; (*B*) Provisions for the Resistance of Wind Force; (*C*) Allocation of Wind Force to Braced Bents; (*D*) Types of Wind Bracing; (*E*) Methods of Analysis of Shallow Wind Bracing Systems; (*F*) Methods of Design for Shallow Wind Bracing Systems; (*G*) Methods of Design for Deep and Mixed Wind Bracing Systems; (*H*) Secondary Stresses; (*I*) Torsional Effects; (*J*) Deflection and Vibration; (*K*) Permissible Stresses; (*L*) Stability; and (*M*) Conclusions and Recommendations.

(*A*) Prescribed Wind Force

1. External Forces on Buildings with Plane Surfaces Normal to the Wind.—In its First Progress Report,[1] the Sub-Committee reviewed at some length the available information respecting the magnitude and character of the wind force that might be exerted on a building and made the tentative recommendation that, including gust effects, the force be considered as a pressure of 20 lb per sq ft on buildings with vertical plane faces for the first 500 ft of height, increased by 2 lb per sq ft for each additional 100 ft.

In consideration of the very serious effects of certain high winds that have occurred in continental United States and in Canada, and the great increase of hazard with increasing height, the Sub-Committee, in its Sixth Progress Report,[2] modified the original wind-force suggestion by recommending that the 20 lb per sq ft applicable for the first 500 ft of height be increased, above this 500-ft level, by 3.5 lb per sq ft for each additional 100 ft of height.

---

[1] *Civil Engineering*, March, 1931, p. 478.

[2] *Proceedings*, Am. Soc. C. E., June, 1939, p. 996.

Still further consideration of the matter led the Sub-Committee to accept the view of Robins Fleming[3] that the increase of the wind force with height should begin at the 300-ft level, rather than at 500 ft. Above 300 ft the force, as finally recommended, increases by 2.5 lb per sq ft for each additional 100 ft of height, thus giving 37.5 lb per sq ft at the 1,000-ft level and 50 lb per sq ft at the 1,500-ft level. The relation of this final recommendation to the previous progress recommendations and to certain other proposals is shown in Fig. 1.

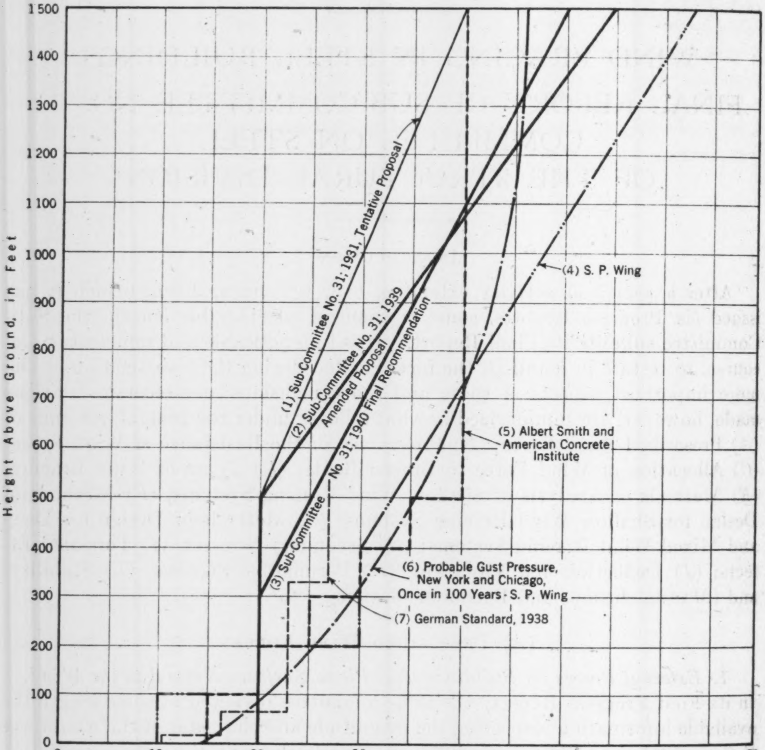

Fig. 1.—Revised Wind Force Proposed for Tall Buildings and Its Relation to Other Proposals

It is to be understood that the wind force recommended herein is in the nature of a minimum standard wind load for the United States and Canada. Special wind-force specifications should be formulated locally for areas that are definitely known to be subject to hurricanes or tornadoes. Sufficient allowance has been made in the prescribed wind force for the effect of air currents striking vertical faces obliquely, either in a lateral or vertical sense.

---

[3] *Proceedings*, Am. Soc. C. E., September, 1939, p. 1279.

From Curve (3), Fig. 1, the adopted wind force of 20 lb per sq ft for the first 300 ft of height corresponds to a wind velocity of only 77.8 miles per hr. Consequently, a substantial amount of shielding is tacitly assumed to exist. Having regard for the uncertainty respecting the permanence of the shelter for any building, and the desirability of having the same basic wind force for the lower portions of tall buildings as for low buildings, the Sub-Committee finally recommends that no additional shielding be assumed and that the omission of wind force for any portion of the height by reason of shielding should not be permitted.

2. Pressure and Suction.—As was pointed out in the First Progress Report,[1] it is not necessary to divide the wind force into pressure and suction effects when dealing with the bracing of tall buildings. However, this may need to be done for structures with rounded roofs, such as armories, hangars, and drill sheds, and for mill or other buildings with large, open interiors and walls in which large openings may occur. For any building, possibly high local suction effects, due to bad aerodynamic properties of the building profile, should be investigated in relation to secondary members and the attachments of roofing or siding.

A study made by the Sub-Committee of the wind forces observed for windward and leeward vertical walls of a large number of models and reported in its Fifth Progress Report,[4] indicated that, where q is the velocity pressure of the wind, an external pressure of 0.8 q may be exerted on the windward wall of buildings of average ratio of height to width and an external suction of 0.5 q on the leeward wall. For an air density of 0.07651 lb per cu ft, corresponding to 15° C, at 760 mm of mercury, and where the velocity V is expressed in miles per hour, the velocity pressure in pounds per square foot is given by

$$q = 0.002558\ V^2 \qquad (1)$$

From Eq. 1, it is seen that the total combined force on the outside of the windward and leeward vertical faces of an average building may be 1.3 q, or approximately,

$$p \doteq 0.0033\ V^2 \qquad (2)$$

On the basis of Eq. 2, the wind velocity corresponding to a wind force of 20 lb per sq ft is 77.8 miles per hr. The velocity pressure for this wind velocity, according to Eq. 1, is 15.5 lb per sq ft.

3. External Forces on Plane Surfaces Inclined to the Wind.—Following a study of all the available experimental data, the Sub-Committee, in its Fifth Progress Report, proposed certain external wind forces on the sloping surfaces of symmetrical gable roofs. These have been slightly revised and have been restated so as to give the force in pounds per square foot, rather than in terms of the velocity pressure. For surfaces not more than 300 ft above the ground and for both symmetrical and unsymmetrical gable roofs, where α is the slope of the roof to the horizontal, in degrees, the recommended wind forces are as follows:

---

[4] *Proceedings*, Am. Soc. C. E., March, 1936, pp. 398–407.

(1) Windward Slope—

(*a*) For α not greater than 20°, a suction of 12 lb per sq ft.

(*b*) For α between 20° and 30°, a force of

$$p = 1.20\,\alpha - 36 \qquad (3)$$

the negative value indicating suction.

(*c*) For α between 30° and 60°, a force of

$$p = 0.30\,\alpha - 9 \qquad (4)$$

the positive value indicating pressure.

(*d*) For α greater than 60°, a pressure of 9 lb per sq ft.

(2) Leeward Slope—

(*a*) For all values of α in excess of zero, a suction of 9 lb per sq ft.

The external wind forces applied to the windward slope are indicated graphically in Fig. 2.

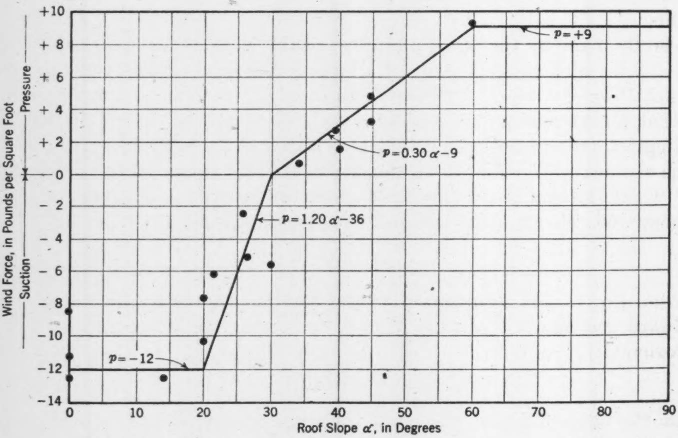

FIG. 2.—RELATION OF EXTERNAL WIND FORCE ON WINDWARD SLOPE OF GABLE ROOF TO ROOF SLOPE

4. External Forces on Rounded Roof Surfaces.—A corresponding study of the observed external wind forces on rounded, or approximately rounded, roof surfaces, reported in the Fifth Progress Report,[4] led to recommendations which in this Final Report are revised and stated in pounds per square foot of surface. Considering the rounded roof as represented roughly by a circular arc passing through the two eaves and the ridge, or, where the roof slope starts from ground level, through the springings and the ridge, and letting the ratio of rise of the arc to its span be r, the recommended wind forces, for surfaces not more than 300 ft above ground level, are as follows:

(1) Windward Quarter of Roof Arc—

(*a*) For roofs resting on elevated vertical supports:

When r is less than 0.20, a suction of 12 lb per sq ft.

When r is greater than 0.20, a pressure of

$$p = 30\,r - 6 \qquad (5)$$

Alternatively, when r is between 0.20 and 0.35, a force of

$$p = 80\,r - 28 \qquad (6)$$

the negative sign indicating suction.

(*b*) For roofs starting from ground level:

For all values of r, a pressure of

$$p = 19\,r \qquad (7)$$

(2) Central Half of Roof Arc—

(*a*) For roofs resting on elevated vertical supports, a suction of

$$p = 15\,r + 11 \qquad (8)$$

(*b*) For roofs starting from ground level, a suction of 11 lb per sq ft.

(3) Leeward Quarter of Roof Arc—

For all values of r greater than zero, a suction of 9 lb per sq ft.

The external wind forces applied to the windward quarter and to the central half of the roof are indicated graphically in Fig. 3.

5. *External Forces on a Flat Roof.*—For a flat roof a normal suction of not less than 12 lb per sq ft should be considered as applied to the entire roof surface.

6. *External Forces on Walls Parallel to the Wind.*—On walls parallel to the wind an external suction of 9 lb per sq ft should be considered.

7. *Internal Wind Forces.*—As was pointed out in the Fifth Progress Report,[4] the wind force to be assumed in design is to be taken as the applicable external wind force (given in paragraphs 3–6) only in case the building is airtight. Such a condition will rarely arise. Normally, air leakage due to the usual small openings around windows, doors, skylights, and eaves will give rise to an internal pressure or suction of from 0.25 q to 0.35 q, depending on whether the openings are chiefly in the windward or in the leeward surfaces.[5] In the rapid building up of gust velocities, the air transfer may be so slow that the internal force is less than this. In standard N–790 of The Netherlands,[5] the external wind forces have all been adjusted to take account of an internal suction of 0.2 q.

Where openings are of substantial size, the internal wind force may be of considerable magnitude. It may be pressure or suction, depending on whether the openings are in windward surfaces, in leeward surfaces, or in surfaces parallel to the wind. Very large internal pressures have been, and may be, built up because of the breaking of windows on the windward side of buildings by reason of flying gravel from the roof or other objects carried by the wind. The Sub-

---

[5] *Proceedings*, Am. Soc. C. E., September, 1936, pp. 1116–1119.

Committee is of the opinion that the only buildings for which the internal wind force should be restricted to the amounts mentioned in the preceding paragraph are those for which the construction is such that the doors and windows cannot be broken in, or with only very small areas taken up by windows and doors.

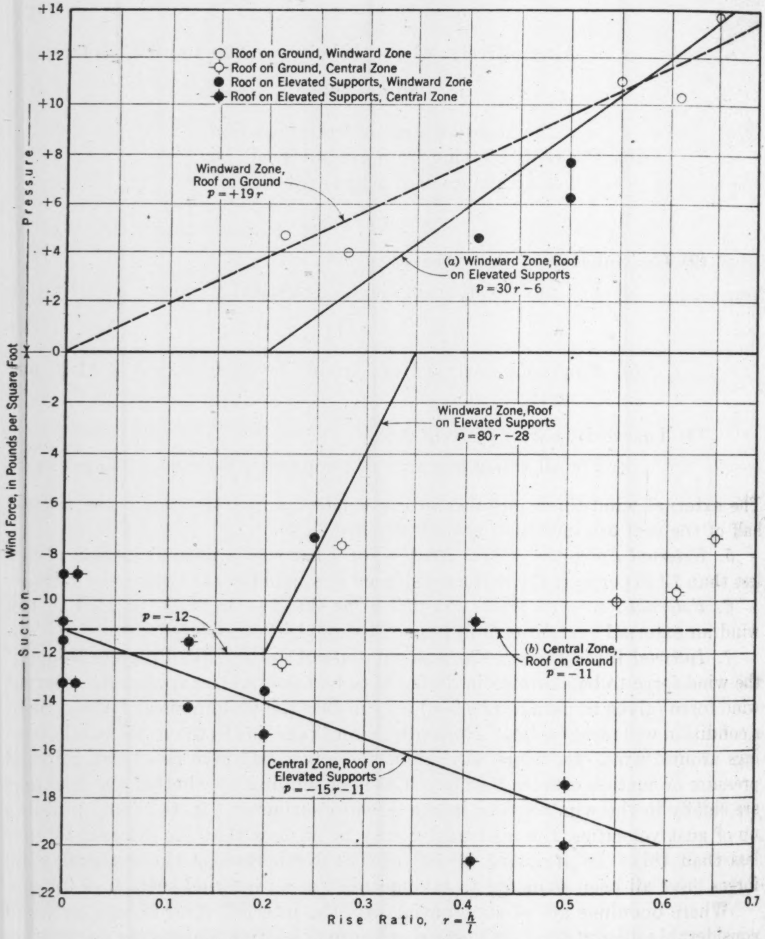

FIG. 3.—RELATION OF EXTERNAL WIND FORCE ON ROUNDED ROOF TO RISE RATIO

Particularly large internal forces may arise when the windward or the leeward side of a building is completely open. The German regulations, effective since June 18, 1938,[6] provide that, for structures which are entirely open on one or more sides, or which can be opened, or which by reason of one or more openings in one or more sides are at least one third open, or can be opened to this extent, a normal internal force of 1.2 q acting outwardly is to be assumed as applied to the underside of the roof. This is in addition to the external suction of 0.4 q on the leeward side of plane roofs, and is specified with a view to insuring proper anchorage of the roof as well as of the attachment of roofing sheets and purlins.

---

[6] Regulations for wind loads contained in DIN 1055, Blatt 4, *Stahlbau-Kalender*, 1939, pp. 182–185.

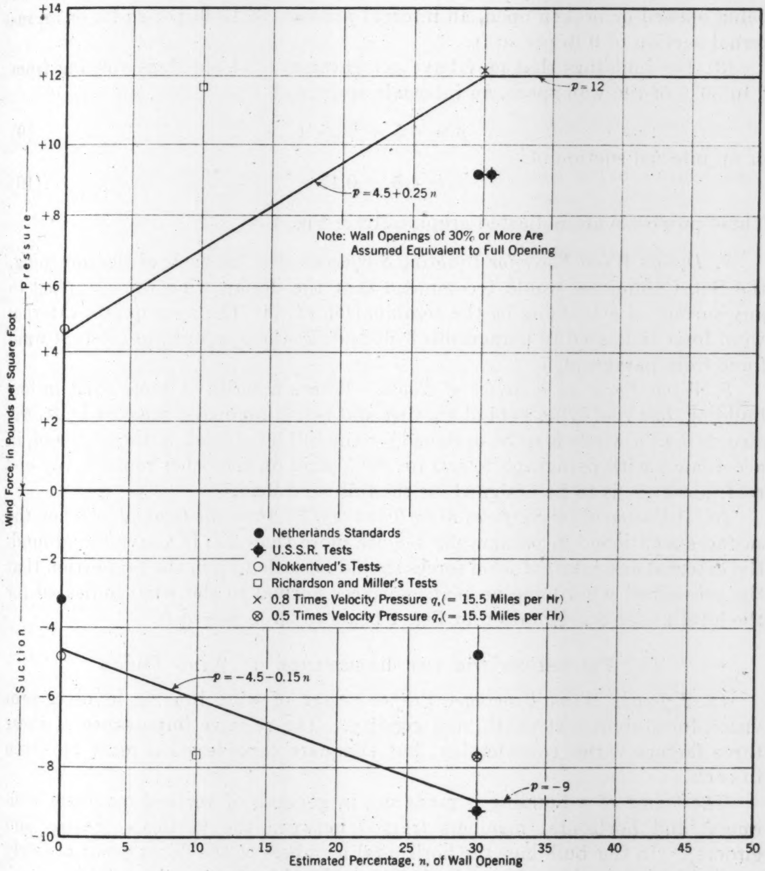

FIG. 4.—INTENSITY OF INTERNAL WIND FORCE

Based upon the investigations reported in the Fifth Progress Report,[4] and on subsequent study and observation, it appears that reasonable allowances for internal wind force would be as follows:

(1) For buildings that, although nominally airtight, with closed doors and windows and unbroken glass, are nevertheless more or less "air leaky," by reason of numerous distributed small openings, an internal pressure or suction of 4.5 lb per sq ft normal to walls and roof.

(2) For buildings with 30% or more of the wall surfaces open, or subject to being opened or broken open, an internal pressure of 12 lb per sq ft, or an internal suction of 9 lb per sq ft.

(3) For buildings that may have percentages, n, of openings varying from 0 to 30% of the wall space, an internal pressure of

$$p = 4.5 + 0.25\,n \qquad (9)$$

or an internal suction of

$$p = 4.5 + 0.15\,n \qquad (10)$$

These proposals are indicated graphically in Fig. 4.

8. Design Wind Force for Building Surfaces.—On the basis of the foregoing, the Sub-Committee would recommend that the design wind force applied to any surface of a building be the combination of: (1) The appropriate external wind force indicated in paragraphs 3–6; and (2) the appropriate internal wind force from paragraph 7.

9. Wind Force on a Series of Roofs.—Where a series of roofs exist in one building, one roof lying behind another and being nominally masked by it, the structure as a whole is to be designed for the full wind load on the first roof, in accordance with paragraph 8, and for 80% wind on the other roofs. Any one roof, however, is to be designed for the full wind load.[7]

10. Adjustment for Surfaces More Than 300 Ft Above the Ground.—When the surfaces mentioned in paragraphs 3–8 are more than 300 ft above the ground, the external and internal wind forces should be scaled up in the proportion that the prescribed wind force on plane surfaces normal to the wind indicated for the level under consideration in Fig. 1 bears to 20 lb per sq ft.

(*B*) Provisions for the Resistance of Wind Force

11. Effective Wind Bracing.—Proper design of wind bracing involves provision for stability, strength, and rigidity. The relative importance of these three factors varies considerably, but adequate consideration must be given to each.

The frame of a building is made up, in general, of vertical members (columns) and horizontal members framed between the verticals (beams and girders). In tier buildings the horizontal members of the floors occur at fairly regular intervals throughout the height and, with the floor slabs, form horizontal diaphragms uniting the columns at each floor level. The purpose of the wind bracing is to preserve this frame from undue distortion when subjected to horizontal forces.

In a building frame as described, the tendency of the panels formed by the columns and their connecting beams or girders to distort, due to horizontal thrust, is resisted by the connections at the columns and by the members in bending and direct stress. Where several columns occur in a line, they form a bent which (to a degree depending on the rigidity of the beams, their connections, and the nature of the bracing utilized) tends to resist the horizontal thrust in the manner of a vertical truss with the columns forming multiple chords, and the columns, beams, and girders forming the web. The columns on the windward side of the axis of the bent become tension chords and those on the leeward side, compression chords.

---

[7] DIN 1055, Blatt 4, p. 2.

In a successful design the building must be assumed to act as a unit, and not distort appreciably when subjected to the applied lateral loads.

12. Floors as Horizontal Diaphragms.—The floors of a building must act as horizontal diaphragms for the delivery of wind-load increments that arise in each story to the braced bents that are provided to receive them. Bracing planes usually run in more than one direction, and the floors must possess the necessary strength and rigidity under loads in their own planes to deliver these wind loads. If the floor is incapable of serving as a horizontal distribution unit, horizontal bracing should be provided between the braced bents. Most of the customary systems of floor construction used in fireproof buildings possess the requisite strength for this purpose.

13. Rôle of Walls and Partitions.—As ordinarily constructed, the walls of a modern tall building cannot be relied upon to absorb any appreciable fraction of the applied wind force. Apart from the uncertainty as to whether the walls act integrally with the frame at the outset, it is obvious that if stressed heavily under horizontal loading they would crack and cease to be a dependable element of strength.[8] In setback buildings, the walls in the planes of the tower sides, of course, are discontinued below the roof of the widened portion of the building. Nor can wind resistance be counted upon for partitions, which, in general, are removable. For these reasons, whatever may be their rôle in lessening deflection and vibration, walls and partitions in buildings having a high ratio of height to width should be ignored in strength calculations, and provision should be made in the structure frame for the entire recommended wind load.

It is recognized, of course, that buildings of low height-width ratio having heavy continuous walls derive much bracing advantage from the walls. Whether added bracing is necessary or not must be left to the analysis and judgment of the designer in each particular case.

(*C*) ALLOCATION OF WIND FORCE TO BRACED BENTS

14. Placement of Wind Bracing.—Whereas in buildings of moderate height-width ratio it is generally possible to adapt sufficient bracing to almost any proposed frame, in tower-like buildings placement of adequate bracing should be given attention in the early architectural studies.

If the floors meet the requirements already given (or in the event that they do not, if they are adequately supplemented by bracing in horizontal planes), there need be no maximum limit of spacing of braced bents, nor any restriction imposed on carrying all the wind force to the end or side walls, if the bracing therein is sufficient to provide for the entire wind force.[9]

---

[8] *Proceedings*, Am. Soc. C. E., June, 1939, p. 1024.

[9] *Civil Engineering*, March, 1931, p. 482.

In order to avoid obstruction of desired clear spaces, bracing often may be placed advantageously in outside walls, or between elevators or around permanent shaft or service areas. Provision can be made in the floor construction for horizontal transfer of shears at offset levels.

15. Wind Resistance in Accordance with Bent Stiffness.—Granted that the floors are capable of serving as effective distribution diaphragms for the applied wind loads, and that the columns at a given floor level remain at fixed distances from one another, the various braced bents passing through the floor can be considered as taking loads in proportion to their rigidities and inversely as the deflections that would be produced in them under equal loads. For symmetrical towers under symmetrical loads the deflection of the braced bents at any floor will be equal and the loads will be distributed in proportion to the bent rigidities.

The method of determining the relative indexes of rigidity was explained carefully in the exposition of the Spurr method in the Appendix of the Third Progress Report.[10]

(*D*) TYPES OF WIND BRACING

16. General.—The type and arrangement of wind bracing required will vary greatly with the size and shape of the building, and the judgment and experience of the designing engineer will have an important influence on its form, placement, and details.

Although it is not practicable to standardize the types of bracing suitable for special buildings, such as armories, hangars, sheds, and mill buildings, certain types are repeatedly used for tier, or multiple-story buildings.

For buildings of moderate height and proportions, shallow bracing involving some form of "knuckle" connections is most frequently used throughout, as was pointed out in the Second Progress Report.[11] This method of providing against wind force entails considerable deflection of the building, and consequently for high or narrow frames the inability of such bracing to hold deflection within reasonable bounds without greatly increasing the column and beam or girder sections makes it very desirable to adopt diagonal bracing of some kind.

Bracing consisting of full diagonals, knee braces, or *K*-frames, with various arrangements in respect of openings in the panel, have been shown in the Second Progress Report. The most effective and economical bracing consists in introducing either single or double diagonals crossing from one intersection of a girder with a column to the diagonally opposite intersection.

17. Combination of Bracing Types.—When gussets, knee braces, or frames are introduced, they add materially to the strength and rigidity of the beams and columns, so that their use tends to concentrate the wind resistance in the panels where they are employed. Although the use of one type of bracing in one panel of a bent and another type in adjoining panels presents no great difficulty, analysis must be based on equal web deflections in such panels, so that the bent may work as a unit.

In the design of wind bracing details the paramount consideration is the lessening of distortion and the prevention of large bent deflections arising therefrom. Desirable practice relating to the design of details was presented in the Second Progress Report.[11]

(*E*) METHODS OF ANALYSIS OF SHALLOW WIND BRACING SYSTEMS

18. General.—For investigating the adequacy of an existing or proposed system of wind bracing, whether properly proportioned or not, a convenient and sufficiently accurate method of analysis must be available. To this end the Sub-Committee has reviewed a number of existing methods applicable to bents with shallow bracing and has developed some others of novel character.

In the Third Progress Report[12] the merits and limitations of the portal and the cantilever methods were discussed and a detailed illustration of the application of the Spurr method to a typical situation was given. The general status of these methods may be stated briefly as follows:

19. The Portal Method.—The portal method, which is generally satisfactory for buildings up to 25 stories in height and of moderate height-width ratio, does not commonly concern itself with elastic relationships. Its virtue lies in simplicity. The assumed distribution of horizontal wind shear is purely arbitrary. With equal beams on equal spans, excess stiffness in the exterior columns tends to increase the shear taken by the outside panels, particularly in low buildings with large story heights, where the columns are relatively flexible and the chord effects are negligible. However, in a high building, the chord action overbalances the web effect of the extra stiff outside columns, and the inside panels actually carry more shear than the outside panels. With irregular column spacing, errors may also occur due to the relation of beam stiffnesses being inconsistent with portal behavior.

20. The Cantilever Method.—The simple cantilever method, which rests on the assumption that the axial wind stresses in the columns, regardless of column areas, are proportional to the distance from the neutral axis of the bent, is generally suitable for buildings of moderate height-width ratio, not more than 25 to 35 stories high. Although it is less frequently used than the portal method, it is more suitable than the latter for high, narrow buildings.

The horizontal wind shears in the various panels are arbitrarily distributed irrespective of the relative stiffness of girders and columns, and of the ability of the girders to transfer increments of column stress as required in cantilever behavior. The degree of accuracy, therefore, will be largely incidental. With equal beams on equal spans, inaccuracy results from the unequal drifts from column and beam bending produced by the assumed stress condition. Unequal beams on unequal spans may cause similar inaccuracies. The resulting design may, or may not, be an improvement from the standpoint of accuracy in any particular case, as compared with the design which would have been obtained by the use of the portal method.

21. The Spurr Method.—For frames having a height-width ratio of 4 or more, increased accuracy of treatment becomes more and more necessary as the slenderness ratio increases. The Spurr method is fundamentally sound for all buildings, since it is based on true elastic behavior and concerns itself with the geometry of distortion. It rests upon the assurance that all members have been so proportioned that the frame will act as a true cantilever and that the floors remain plane during and after deflection. It may be used in whole or in part for buildings of moderate height.

---

[12] *Proceedings*, Am. Soc. C. E., December, 1933, p. 1618.

In an elastic structure of multi-story type which is subjected to horizontal wind forces, the true moments and shears in the various members are dependent upon the relative rigidities of all the members, if they are properly connected. Inelastic action or slip in the connections will affect the distribution of stresses throughout the structure, and such effects are to be guarded against as far as possible by care in the design of the connections. Elastic action in the connections, whether deep or shallow, or in knee braces or frames, is unavoidable, and quite properly such effects should be ascertained and evaluated in the design.

In high frames the change in length of columns under axial wind stresses is an important element. In real wind problems, such as are presented by high, slender frames, the aim should be the creation of a design which is "prudently" or "correctly" proportioned. In a frame so proportioned, the change in length of columns will have no material effect upon the web analysis. On the other hand, a badly proportioned frame will produce irregular changes in the lengths of columns under axial wind stresses, which condition will make it practically impossible to obtain an accurate analysis.

From a practical standpoint, therefore, it is essential that the elastic proportions of the web system be controlled in such a manner as to simplify the calculations. This is readily done by an assumed distribution of the horizontal wind shears throughout the structure so as to maintain a plane after bending in the various wind bents. If the building is to act as a unit, all bents must deflect alike.

The primary objective of the Spurr method, which is in reality more a method of design than one of analysis, is to insure that each wind bent acts as a true cantilever. Once this condition is attained, the investigation of stresses and deformations is simplified very greatly.

22. The Cross, Goldberg, and Grinter Methods.—In the Second Progress Report, a comparison was made of the stresses originally calculated by slope deflection in the classic 20-story Wilson and Maney bent with those found by the Cross method of distributing end moments.[13] This showed the entire sufficiency of the Cross method, provided that secondary bending stresses due to column axial distortion from wind are ignored. The greatly increased speed of calculation as compared with the slope-deflection method was particularly apparent. A concise statement of the successive steps to be taken in the application of the Cross process was presented in the report.

The Sub-Committee also examined other methods based upon theoretical considerations. In the Fifth Progress Report[14] the applicability of the Goldberg[15] and Grinter[16] methods was discussed. The method introduced by Henry V. Spurr, M. Am. Soc. C. E., in 1930,[17] which takes account of the axial distortions of columns due to wind, was outlined in some detail in the Third Progress Report.[18]

[17] "Wind Bracing, the Importance of Rigidity in High Towers," by Henry V. Spurr, McGraw-Hill Book Company, Inc., New York, N. Y., 1930.

23. Witmer Method of K-Percentages.—In the Sixth Progress Report,[19] consideration was given to the relation between the vertical wind reactions developed at the various columns of a symmetrical 4-column bent under the action of wind forces. These relations were determined in connection with varying dimensions of bent and varying sizes of girders and columns, the relations being derived by theoretical considerations, as well as from experimental tests of model bents made by Francis P. Witmer, M. Am. Soc. C. E., and Harry H. Bonner.[20] Diagrams were presented to facilitate computation of wind reactions for such bents.

Careful consideration was also given to the relations between vertical wind reactions of columns and actual dimensions for bents, both symmetrical and unsymmetrical, and with varying numbers of columns. Conclusions were based upon theoretical grounds by a consideration of the behavior of the bents as determined by the Cross method of analysis. A routine procedure called "a method of K-percentages" was described, based upon the actual sizes and dimensions of the bent, by consideration of which the vertical wind reactions at all columns might be obtained with reasonable accuracy. From these reactions, by a statically determinate process, the wind moments may be readily computed. For bents having a wide variety of proportions, these moments were found to be in sufficiently close agreement with results obtained by rigid theory to be considered generally permissible, and by reason of their rational basis to be preferable to those found by the older, approximate portal and cantilever methods, which used reactions developed according to some arbitrary assumption of behavior, regardless of the actual sizes in the bent.

It should be pointed out, with reference to a comment of Samuel T. Carpenter,[21] Assoc. M. Am. Soc. C. E., that, although the method of K-percentages was not derived from any concrete mathematical formula, it had its origin in phenomena discovered to be inherent in the application of Cross analyses to a great number of differently proportioned bents. As stated in the Sixth Progress Report,[19] it was observed that in every case the ratios of vertical wind shears in the different bays changed in value very slightly from cycle to cycle, and that their value as found from a simple consideration of the stiffness factors of the girders and columns was practically the same as after a complete Cross analysis. The sufficiency of a 3-story compromise bent for determining these shear ratios, and therefore the vertical wind-reaction ratios, was inferred after a comprehensive experimental study of Cross-analyses phenomena in such bents.

The engineer is not always concerned with the preparation of a new design. His duties frequently call for an investigation of an existing structure or the check of another's design whose method of computation is not known to him. He must then compute wind stresses with nothing before him except a set of actual or designed sizes. In such a case, unless the sizes happen to be in such relation as to develop the cantilever type of reactions, the Spurr method will be inapplicable. Then the only recourse generally would be to one of the more laborious rigid theoretical methods. In this contingency it is believed that the proposed method of *K*-percentages may prove of practical value. The preliminary design required before this method can be applied should not constitute an insuperable objection. Such a condition is inherent in practically all bridge designing problems which involve structures of a statically indeterminate character, and the Spurr method itself is not free from this requirement, as the sectional areas of columns must be determined before wind reactions in accord with the cantilever principle can be found.

---

[18] *Proceedings*, Am. Soc. C. E., December, 1933, p. 1611.

[19] *Loc. cit.*, June, 1939, p. 969.

[20] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 416.

[21] *Proceedings*, Am. Soc. C. E., November, 1939, p. 1635.

Discussions of the Sixth Progress Report have indicated that the method of *K*-percentages might be considered to possess practical utility. In this matter, however, the intention of the Sub-Committee has not been to advocate a new method of computation as a substitute for those already in use, but rather to indicate the desirability and practicability of determining at the outset, with reasonable correctness, all external reactions resulting from any assumed set of wind forces acting upon a bent of any assumed proportions. Wind moments computed from these reactions are considered to have a more dependable basis than those found by the older approximate methods, while at the same time the great expenditure of time and labor required by methods which are in more or less precise accord with rigid theory is avoided.

24. Applicability of the Various Methods to the Problem of Analysis.—Methods of computation are so largely a question of individual judgment among engineers that the Sub-Committee hesitates to recommend one method in preference to another. In view of the studies which it has made with regard to bents having small connections in pure bending, however, it feels justified in offering the following suggestions which bear upon the appropriateness of specific methods under certain specific conditions:

(1) If a preliminary design of the bent is made to accord with vertical floor loads alone, with an assumption of discontinuous girders, and with certain other assumptions as recommended by Professor Witmer in a discussion of the Fifth Progress Report,[22] and if, furthermore, secondary moments due to axial distortion of the columns under direct wind stress are neglected, direct wind stresses and vertical wind reactions in the interior columns may be considered equal to zero and the bent may be properly analyzed for primary wind stresses by the portal method.[22, 23]

(2) If the bent has been proportioned by the Spurr method,[17] true cantilever behavior will exist, floors will remain practically plane, and the secondary bending stresses from column axial distortion will be negligible and properly may be ignored.

(3) If any other method of designing is adopted than is described under paragraphs (1) or (2), and if wind stresses are then computed by assuming arbitrarily a particular behavior of the bent under wind, without due consideration of the relative sizes of girders and columns, there is no assurance whatever that the assumed behavior will be realized. Consequently, wind reactions and resulting stresses from wind will be without theoretical justification.

---

[22] *Proceedings*, Am. Soc. C. E., November, 1936, pp. 1496–1498.

[23] *Loc. cit.*, March, 1936, p. 409.

(4) If a preliminary design is first made upon any selected basis, primary wind stresses always may be computed by any of the rigid theoretical methods or their modifications—for example, by the slope-deflection method or by the methods of Cross,[13] Goldberg,[15] or Grinter.[23] Of these methods, slope deflection is the least practicable from a standpoint of time and labor required. The Cross method is far more advantageous in these respects, but is still very laborious. The Goldberg and Grinter methods offer abbreviations in the amount of work with some compensating loss in exactness, but the Sub-Committee's study of them indicated that they possess practical advantages and produce substantially correct results.

(5) Having a preliminary design made by any assumed method, or an existing structure whose method of design is unknown, primary wind stresses may be computed very readily and with sufficient theoretical correctness by the method of K-percentages.[19]

(*F*) METHODS OF DESIGN FOR SHALLOW WIND BRACING SYSTEMS

25. Non-Elastic Methods.—Having assumed the proper applicability of one of the methods of analysis outlined in part (*E*) of this Report, the determination of wind moments, shears, and thrusts and the proportioning of members and details naturally follows, subject, of course, to whatever inexactness may be involved in the theory adopted. Methods that ignore the elastic properties of the bent, such as the portal and the simple cantilever methods, have distinct limitations, as was stated in paragraphs 19, 20, and 24.

26. The Spurr Method.—Assurance of bent behavior in accordance with theoretical assumptions can be had with all necessary accuracy by proportioning according to the Spurr method, which is in accordance with the principles of elasticity. A preliminary design is required only for columns in order to obtain their sectional areas, from which vertical wind reactions can be determined that will be in keeping with the cantilever theory. The complete design may then be made in accordance with the elastic principles upon which the method is based and, in consequence, the relation of reactions will be the same in the finished structure as in the preliminary design.

To produce the reactions that are associated with true cantilever action, a definite relation must exist between the moments of inertia of girders in the several bays of any floor, and this always will require relatively larger girders in some bays than would be required for vertical floor loads alone.[20] The net effect of this condition upon the ultimate economy of the design cannot be ascertained without further investigation. There would appear to be justification for an inference that this method might lead to some loss in economy as compared with a bent designed in accordance with paragraph 24 (1). The Spurr method, however, has a further advantage of controlling the rigidity of the bent against horizontal deflection. If design upon the principles of the Spurr method is desired, an *a priori* determination of the approximate relation between moments of inertia of girders in the several bays may be obtained readily by use of the formula ΣI varies as $V_g L_g^2$, having first found values of V_g by the cantilever theory.[24]

---

[24] *Proceedings*, Am. Soc. C. E., June, 1939, p. 977, and Fig. 5(*d*), p. 983.

In following the Spurr method,[25] the designer's first step should be the preparation of preliminary plans and a column schedule based on dead-load and live-load requirements. The next step is the selection of vertical bents in the frame in each direction which can reasonably be expected to act in resisting the wind. The relative rigidities of the several bents should then be ascertained, based on the analysis of the bents for chord deflection. The proper percentage of the total wind load on the structure should be distributed to each bent in such a manner as to make the chord deflections equal, based on the assumption that horizontal planes through the bents remain plane after bending. Usually, the web deflections of the several bents (that is, the deflection due to the distortion of the beams and their connections and the bending of the columns) can be made alike by "tuning," so that the bents will give equal deflections under the allocated loadings. This principle must hold whether deep or shallow bracing is used. To this end it may be necessary to stiffen some panels and loosen others.

The foregoing conditions determine the amount of wind shear in the various panels of each bent throughout the structure. The web system should then be designed to produce the same drift in all panels in any one story. With the wind shears in the panels of each bent fixed, the web deflections in all panels of the bent must then be the same. In extremely high and slender buildings the designer should consider the necessity of placing a limitation upon the static deflection permitted under the design load.

(*G*) METHODS OF DESIGN FOR DEEP AND MIXED WIND BRACING SYSTEMS

27. General.—Since for equal deflections deep bracing is much more economical than shallow bracing, it should be used whenever practicable. The wind force and the possible effect of gravity loads may be readily cared for in the design in accordance with statical principles.[17]

Complications of building layout often render uniformity of type in wind bracing for different parts of a frame impossible of attainment. Several different types may be used in the various bays of a braced bent in one story but, so, the design should be in accordance with the principle that the estimated web deflections in the various bays should be the same.

(*H*) SECONDARY STRESSES

28. General.—In recent years, considerable thought has been given to more exact methods of design and analysis, especially the latter. Columns and beams subject to bending moments bend, and members subject to direct axial stress change in length. Such actions in the frame have a direct bearing on the distribution of wind shears, and, consequently, on the bending moments in the members.

In attempting to arrive at a more accurate analysis of frame action, the slope-deflection and the Cross methods were developed, both aiming to reach true shear distribution. Both methods are somewhat cumbersome in application for many-storied frames, and, to keep them at all workable, the assumption is usually made that the joints remain fixed in elevation and that there is no change in length of any of the members.

---

[25] *Proceedings*, Am. Soc. C. E., December, 1933, pp. 1621–1631.

In a high building which has been proportioned without due attention to the need for establishing such elastic relationships as will lead to regularity in the vertical movements of the successive floor joints, these movements will be irregular and not readily calculable. The existing complexity is evident when it is remembered that not only do the vertical reactions of the web system upon the columns affect the movement of the joints, but these movements affect the reactions. It is true, unfortunately, that an accurate analysis of an injudiciously proportioned frame of many bents and stories is a difficult and impracticable task.

In actual wind problems the aim should be the creation of a design that is so proportioned that the floor joints will move in a predetermined and regular manner in order that the predetermined stresses may be realized. An elastic relationship yielding this desirable result is attained when the floor joints are maintained in a plane after bending. Such action is possible only when the web system is so proportioned and connected to the columns as to transfer to them the vertical increments of load consistent with true cantilever action. Consequently, the beams in the interior panels must be more rigid than those in the exterior panels. As stated in paragraph 21, the Spurr method of design[25] produces a bent which will maintain planarity of floors and in which the lengthening and shortening of the columns will not affect the accuracy of the calculations.

Unless the bent acts as a cantilever under wind, as assumed in the Spurr method, secondary wind moments can be computed only by a second operation after primary direct wind stresses in columns have first been found by some other process, as the *K*-percentage method. This can be accomplished by applying the Cross method to the axial wind distortions in columns, thus determining separately the secondary moments by which the primary moments should be corrected.[13] This is a laborious process. It is believed that a satisfactory abbreviated procedure may be devised for the purpose but, so far, this has not been achieved.

29. Relative Magnitude of Secondary Effects.—According to the portal method of design, which allocates all the column direct stresses to the exterior columns, and consequently produces the same shear in all panels of the bent, the axial deformations of the exterior columns due to wind stress result in nonplanarity of floors and secondary moments in the members. George E. Large,[26] M. Am. Soc. C. E., has investigated the effect of direct deformation of the columns on the wind stresses in portal-designed bents, and states:

> "The results of two investigations conducted upon portal-designed bents show that correction for the direct deformation of columns is hardly necessary in bents of height to base ratios less than 5, while for bents twice as slender the corrections should be made to avoid large errors in girder shears, on the side of danger."

The investigations of Professor Large show that there is a decided tendency for a portal-designed bent of three equal panels to swing over to cantilever action. This results in errors in the assumed girder shears of from 10% to

15% in a 26-story bent with a height-width ratio of 5, and errors as high as 41% in a 55-story frame with a height-width ratio of 10.

(*I*) Torsional Effects

30. General.—Buildings which are symmetrical about two axes, both as to exterior and as to arrangement of bracing, are unusual, except for monumental towers and free-standing tower buildings. Even on a symmetrical building the distribution of the wind pressure is not uniform, due to surrounding structures and to eddies caused by the building itself. Although the wind pressure may act symmetrically over the face of a building, if the building is unsymmetrical in plan about an axis parallel to the direction of the wind, the eccentricity of the center of rotation of the building with respect to the resultant wind force will cause torsion and unsymmetrical stress distribution. If the building is unsymmetrical about both axes, a wind from any direction will cause torsion.[27]

31. Method of Analysis.—An analysis of torsional stress distribution, based upon the work of Albert Smith,[28, 29] M. Am. Soc. C. E., was prepared by Professor Large and published in the Sixth Progress Report of the Sub-Committee,[30] to which attention is directed.

As a result of the analysis mentioned, it appears that, although a rapid and often sufficiently accurate method may be based upon the neglect of all deformations except girder bending, it is desirable to include the effect of axial length changes of the columns. Professor Large found that over-all economy does not lie in the elimination of torsional moment by the stiffening of certain bents so as to move the torsional center to the line of action of the resultant wind force.

(*J*) Deflection and Vibration

32. General.—Quite apart from the obvious necessity for providing adequate strength in structural members and details and for the proper distribution of wind forces among the bents, care must be taken to insure that deflections and vibrations are kept within such limits as render tall buildings comfortably habitable.

Only experience will reveal the relation between computed maximum deflection and comfortable occupancy. By reason of the present impossibility of appraising in advance the restraining or damping effect of the non-skeleton parts of a building upon deflection, it is convenient to use, as a measure of the stiffness, the relation between the maximum deflection of the top of the frame and its height, assuming the frame to carry the entire lateral force. This might perhaps be called the "deflection index." Because of the damping effect of walls, partitions, and floors, it does not represent the actual deflection, but some multiple of that quantity. Nevertheless, it is a convenient standard by which to judge the probable stiffness of a building.

It has been found that tall buildings with a deflection index of 0.002 under assumed triangular loadings somewhat lighter than those recommended by the

Committee have a satisfactory behavior in the matter of deflection and vibration. In very high buildings, this value represents not only a satisfactory occupancy basis, but about the upper practicable limit of attainable stiffness without large additions to the girder sizes for wind effect only. It is possible that higher theoretical frame deflections would be tolerable, but relaxation in this regard should come only as a result of accumulated experience.

Instances are known of well-designed buildings of 20 to 25 stories in height, having deflection indexes upward of 0.004 or 0.005 that have behaved satisfactorily. In addition to securing comfortable occupancy, a proper limitation of deflection guards against injury to internal and external masonry.[8]

33. Computation of Deflections.—Although, as previously stated, the actual deflection of a building is only a fraction of that computed, nevertheless the computed deflections of the bents under a unit wind load provide the only rational basis for apportioning the total wind force among the bents, and for judging flexibility.

The theoretical deflection of a wind bent is due to (1) chord action and (2) web action. The former arises from direct lengthening and shortening of the columns, whereas the latter arises from (*a*) reverse bending of girders, (*b*) reverse bending of columns, and (*c*) deformation of connections and bracing.

34. Chord Deflection.—In designing a tall building, the chord deflection of each bent due to a unit loading is computed as soon as the column schedules for dead load plus live load are available. Then the wind is divided among the bents inversely as the chord deflections, thus producing the same chord deflection for all bents. Ultimately, the girder and connections are so selected that the deflection of all bents due to web action is also a uniform amount. Thus, the total computed deflection of the structure is the same for all the bents, which satisfies elastic requirements.

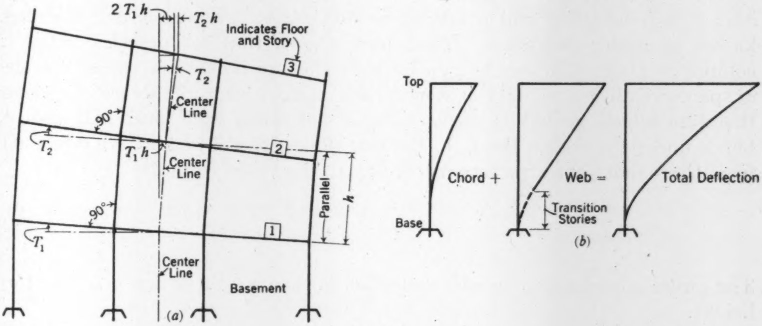

FIG. 5

A useful method of computing chord deflection is that developed by Professor Large.[31] Proceeding in accordance with it, and remembering that chord deflection results from the accumulation of column direct deformation throughout a number of stories, consider first the basement story, in which the generation of the tilt angle T_1, Fig. 5(*a*), causes a lateral deflection at the ceiling of story 1 of $T_1 h$. Then, after the next story deforms, the deflection at the ceiling of story 2 equals $2 T_1 h + T_2 h$, etc., if h is constant. The lower stories make the largest contribution to total chord deflection, measured at the top of the bent, (*a*) since their high column unit stresses produce comparatively large tilt angles, T, and (*b*) because their "leverages" to the top of the bent are longest. Fig. 5(*b*) shows the shape of the deflection curves. Contrary to popular conception, the upper portion is practically straight.

---

[31] "Tests and Design of Steel Wind Bents for Tall Buildings," by George E. Large, Samuel T. Carpenter, and Clyde T. Morris, *Bulletin No. 93*, Eng. Experiment Station, Ohio State Univ., p. 24.

35. Chord Deflection Formula.—For regular bents subjected to a uniformly distributed wind load, the overturning moment is proportional to the square of the distance from the top of the bent. Column areas will be very nearly directly proportional to the same distance. Consequently, the unit chord stress in a column increases directly with the distance measured down from the top. At the top of such a bent the chord deflection may be shown to be:[31]

$$\Delta_c = \frac{2\,s\,h^2}{3\,E\,L} \qquad \text{(11)}$$

In this expression s is the wind unit chord stress in the outside column at the base of the bent, h is the height of the bent, L is the base width of the bent, and E the modulus of elasticity.

An examination of Eq. 11 will show that, of two bents differing only in base width and number of panels, if one has half the width of the other, it can be assigned only one fourth as much of the wind load. The expression may also be used in an investigational manner to find approximate chord deflections for injudiciously proportioned bents. When so used, it should be applied only to the outside columns.

36. Web Deflection.—Unless a wind bent is very slender, the largest single item of web deflection will ordinarily be that due to reverse bending of girders, known as girder deflection. Tests have shown that for practical ratios of column to girder stiffness, the girder contraflexure points are near the center of span, even in the vicinity of structural irregularities.[32] The careful designer therefore selects girders of such stiffness that when each clear half span, b, bends under the design shear, V, the end slopes, θ, will be approximately uniform throughout the structure, according to the Spurr formula:

$$\theta = \frac{V\,b^2}{3\,E\,I} \qquad \text{(12)}$$

The girder contribution to web deflection is then $\theta\,h$, in which h is the story height.

Because of the appreciable distance between the end of a girder and the center of joint rotation on the geometric axis of a column, the girder end is displaced vertically as the angle θ develops. The net effect of this phenomenon is to diminish the girder contribution to web deflection. Mr. Spurr recognizes this by conveniently deducting 6 in. from the clear half span to obtain the bending length, b, to use in Eq. 12. This practice has been demonstrated to be satisfactory from a theoretical standpoint.[33]

---

[32] "Tests and Design of Steel Wind Bents for Tall Buildings," by George E. Large, Samuel T. Carpenter, and Clyde T. Morris, *Bulletin No. 93*, Eng. Experiment Station, Ohio State Univ., pp. 26–33.

The columns also bend in reverse curvature under wind, although their contribution to web deflection is seldom greater than 10% of that of the girder system. Their principal contraflexure points have been found by test to lie quite close to the midstory level, except in the vicinity of structural irregularities, such as fixed bases[34] and setbacks. Columns bend over their full lengths, and have minor contraflexure points near the midheight of the split-I, shallow connection to the girder, or at about half the depth of a knee brace.[35] Eq. 12 is also correct for computing column end slopes, if clear half lengths are used.[33] The resulting angle, θ, is measured from a straight line connecting the two ends. The column contribution to web deflection is then $\theta\, h$.

Little is known about the elastic deformation of wind connections, particularly split-I, shallow connections. The tests of J. Charles Rathbun,[36] M. Am. Soc. C. E., showed angular deformations as great as 1 : 1,000 under the design moment specified by the American Institute of Steel Construction. This is considerably more than the 1 : 6,000 design value sometimes used by Mr. Spurr[17] and suggests that such connections may contribute as much to web deflection as the girders. So long as this uncertainty exists, an ideal practice of arranging column spacing, which will produce the same wind moment and, therefore, identical wind connections entirely across a floor, should be encouraged, particularly for slender towers.[28]

37. Deflection of Lower Stories.—Fig. 5(b) is intended to show that a uniform web deflection of, say, 0.0015 h will not exist in lower stories just above a fixed base. Depending upon conditions, the designer needs from 3 to 6 stories to make the transition[32] to the established slope; and in these stories the location of the contraflexure points of the columns must grade gradually from a very high location in the basement story to the midstory level in the uppermost transition story. In these situations, a scale layout drawn with angles and deflections exaggerated about 400 times is very helpful.

38. Investigation to Find Web Deflection.—The foregoing discussion of web deflection has been addressed to the designer, who presumably is free to make the computed deflections whatever he prefers. The investigation of an existing slender bent for stress and deflection is more difficult; and in the case of bents originally proportioned with utter disregard for elastic requirements a satisfactory solution may be practically impossible, due to unmanageable direct deformation of columns.

(*K*) PERMISSIBLE STRESSES

39. Permissible Stresses for Combined Loading.—Careful consideration has been given to the discussion of the permissible stresses proposed by the Sub-Committee, and, having regard to all the facts, the recommendations contained in the Second and Third Progress Reports[13, 37] are here reiterated. They are as follows:

---

[33] "Tests and Design of Steel Wind Bents for Tall Buildings," by George E. Large, Samuel T. Carpenter, and Clyde T. Morris, *Bulletin No. 93*, Eng. Experiment Station, Ohio State Univ., p. 46.

[34] *Loc. cit.*, pp. 26–27.

[35] "Settlement Stresses in Continuous Frames," by George E. Large, *Bulletin No. 102*, Eng. Experiment Station, Ohio State Univ.

[36] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 542.

For members or details subject to wind stress only, except rivets and bolts, the permissible stress should be the same as that allowed for dead load or for dead load and live load.

For members subjected to stresses arising from the combined similar action of wind and other loads, and for rivets and bolts subject to wind stress, the wind stress up to $33\frac{1}{3}\%$ of the other stresses may be neglected, the excess wind stress being considered as equivalent to an added live-load stress, provision being made for it at the basic working stress for dead load and live load only.

A somewhat higher fraction of the wind stress may be neglected in the case of the columns of very high buildings, the exact amount being best left for the determination of the designing engineer in the light of all the circumstances.

Members subject to a combination of wind, dead load, and live load, of course, should have a section not less than the section required for dead load and live load alone at the normal working stress.

40. Members Subject to Combined Axial and Bending Stress.—Columns will be required to resist axial loads that arise from both gravity and wind effects and at the same time to resist wind moments, while girders will be called upon to resist moments due to both gravity loads and wind loads and, in addition, a wind thrust. It is necessary that the design of these members for the combined effects of the loads mentioned should be consistent with the proportioning of members for axial stress only, at the foregoing permissible stresses. This will be realized if

(*a*) All columns are proportioned, at the normal working compressive stress for dead load plus live load, for a hypothetical axial load equal to

$$P = \frac{2}{3} P_g + P_w + \frac{M_w d}{2 r^2} \dots\dots\dots\dots\dots\dots (13)$$

(*b*) All girders are proportioned, at the normal working flexural stress for dead load plus live load, for a hypothetical moment equal to

$$M = \frac{2}{3} M_g + M_w + \frac{2 P_w r^2}{d} \dots\dots\dots\dots\dots\dots (14)$$

in which: P_g = axial gravity load; P_w = axial wind load; M_g = gravity load moment; M_w = wind moment; d = depth of girder, or width of column; and r = radius of gyration in the direction of bending. In no case should the section selected be less than that required for gravity load effects only.

(*L*) STABILITY

41. Factor of Safety.—In order that a building may be secure against overturning, the Sub-Committee recommends that the factor of safety against uplift be not less than 1.5. In other words, the axial tension due to wind load in the critical column should not be more than two thirds of the dead-load compression

---

[37] *Proceedings*, Am. Soc. C. E., December, 1933, p. 1603.

in the bottom story of the column, unless the columns are securely anchored to the foundation by anchors proportioned at the permissible stress applicable to members carrying wind load only. Moreover, the foundation itself should be adequate for 1½ times any uplift that may be imposed on it.[38]

(*M*) CONCLUSIONS AND RECOMMENDATIONS

The principal conclusions and recommendations of the Sub-Committee are as follows:

(1) As a standard wind load for the United States and Canada the Sub-Committee recommends a uniformly distributed force of 20 lb per sq ft for the first 300 ft above ground level, increased above this level by 2.5 lb per sq ft for each additional 100 ft of height, no omission of wind force being permitted for the lower parts of the building by reason of alleged shelter. Special wind-force specifications should be formulated locally for areas that are definitely known to be subject to hurricanes or tornadoes.

(2) For proportioning the wind bracing of tall buildings it is not necessary to divide the wind force into pressure and suction effects, although this should generally be done for structures with rounded roofs, for mill or other buildings with large open interiors, and for walls in which large openings may occur. The effects of possible high local suction should be investigated in relation to secondary members and the attachment of roofing or siding.

(3) For plane surfaces inclined to the wind and not more than 300 ft above the ground, the external wind force may be pressure or suction, depending on the exposure and the slope. For a windward slope inclined at not more than 20° to the horizontal, a suction of 12 lb per sq ft is recommended; for slopes between 20° and 30° a suction uniformly diminishing from 12 lb per sq ft to zero; and for slopes between 30° and 60° a pressure increasing uniformly from zero to 9 lb per sq ft. For the leeward slope, for all inclinations in excess of zero, a suction of 9 lb per sq ft is recommended.

(4) For roofs that are rounded, or may be represented roughly by a circular arc passing through the two springings and the eaves, the wind force will depend not only upon the exposure and the ratio of rise to span of the equivalent circular arc, but also upon whether the springings are elevated above the ground or are on the ground. Where the surfaces considered are not more than 300 ft above ground level the recommended external wind force is as follows:

(*a*) On windward quarter of the roof arc, when the roof rests on elevated vertical supports and where the rise ratio is less than 0.20, a suction of 12 lb per sq ft is recommended; and for a rise ratio varying from 0.20 to 0.60, a pressure increasing uniformly from zero to 12 lb per sq ft, or, alternatively, for rise ratios between 0.20 and 0.35, a suction varying uniformly between these limits from 12 lb per sq ft to zero is recommended. For roofs springing from the ground level a pressure, for rise ratios varying from zero to 0.60, uniformly increasing from zero to 11.4 lb per sq ft, is recommended.

---

[38] *Proceedings*, Am. Soc. C. E., February, 1932, p. 215, and *Loc. cit.*, December, 1933, p. 1606.

(*b*) For the central half of the roof arc, where the roof rests on elevated vertical supports, with rise ratios varying from zero to 0.60, a suction uniformly varying from 11 lb per sq ft to 20 lb per sq ft is recommended; for roofs starting from ground level, a suction of 11 lb per sq ft, regardless of the rise ratio, is recommended.

(*c*) For the leeward quarter of the roof arc, for all values of the rise ratio greater than zero, a suction of 9 lb per sq ft is recommended.

(5) It is recommended that for a flat roof a normal external suction of not less than 12 lb per sq ft should be considered as applied to the entire roof surface.

(6) On walls parallel to the wind it is recommended that an external suction of 9 lb per sq ft should be considered.

(7) Even for buildings that are nominally airtight, internal wind forces of either pressure or suction may exist, varying from 3 to 6 lb per sq ft, and depending on whether the openings are generally in the windward or in the leeward surfaces. Large internal pressure may arise due to the breaking of windows in the windward side of buildings by reason of flying gravel from the roof or other objects carried by the wind. Still larger internal forces of pressure or suction may arise when the windward or leeward side of a building is completely open. The Sub-Committee recommends that for buildings that are nominally airtight an internal pressure or suction of 4.5 lb per sq ft should be considered as acting normal to the walls and the roof. For buildings with 30% or more of the wall surfaces open, or subject to being open, an internal pressure of 12 lb per sq ft, or an internal suction of 9 lb per sq ft, is recommended; for buildings that have percentages of wall openings varying from zero to 30% of the wall space, the recommendation is an internal pressure varying uniformly from 4.5 to 12 lb per sq ft, or an internal suction varying uniformly from 4.5 to 9 lb per sq ft.

(8) The Sub-Committee recommends that the design wind force applied to any surface of a building be a combination of (*a*) the aforementioned appropriate external wind force, and (*b*) the appropriate indicated internal wind force.

(9) Where a series of roofs exists in one building, one roof being nominally masked by another, the structure as a whole should be designed for the full wind load on the first roof and for 80% of the wind load on the other roofs. Any one roof should be designed for the full wind load.

(10) When wind surfaces are more than 300 ft above the ground, the external and internal wind forces should be scaled up in the proportion that the prescribed wind force on plane surfaces normal to the wind fixed by recommendation (1) at the level under consideration bears to 20 lb per sq ft.

(11) The capability of the floors to serve as horizontal diaphragms for the delivery of wind-load increments in each story of the braced bents should be investigated. If they appear to be inadequate, an efficient system of horizontal bracing should be provided between the braced bents to distribute the load.

(12) Although walls and partitions may serve to lessen vibration and deflection, they should be ignored in strength calculations for buildings having a

high ratio of height to width and provision should be made in the structural frame for the entire recommended wind load.

(13) If floors, with or without added bracing, are sufficient to serve as effective horizontal diaphragms, there need be no maximum limit of spacing of braced bents, nor any restriction imposed on carrying the wind force to the end or side walls, if the bracing therein is sufficient to provide for the entire wind force.

(14) If the floors are capable of serving as effective distribution diaphragms, the various braced bents may be considered as taking loads in proportion to their respective rigidities. The allocation of wind load to braced bents should take into consideration the eccentricity of the total lateral load to the lines of resistance.

(15) Although shallow bracing may be of sufficient strength, it may entail excessive deflection of the building. Consequently, for high or narrow frames, it is very desirable to adopt diagonal bracing of some kind. Full diagonals, knee braces, or K-frames, with various arrangements in respect of openings in the panel, may be used advantageously. Although the use of one type of bracing in one panel and another type in adjoining panels is permissible, the calculated web deflections in all the panels in any story of the bent should be the same, so that the bent may work as a unit.

(16) Although adequate over-all strength may be provided by wind bents designed in accordance with either the portal or the simple cantilever method, the assumptions upon which these methods rest do not ordinarily make possible a properly balanced design. These methods, however, are useful for making a rapid strength analysis.

(17) Investigation of frames having a height-width ratio of 4 or more by some method recognizing the elastic properties of the bent is necessary. If a bent has been so proportioned that it will act as a true cantilever and the floors remain plane during and after deflection, the problem of investigation is greatly simplified, in that secondary stress calculations are obviated.

(18) For purposes of analysis the Cross method of moment distribution has been found to be highly valuable, although for tall frames the large number of cycles necessary to effect a sufficiently accurate solution renders it impracticable. Both the Goldberg and the Grinter methods make it possible to effect a rapid and sufficiently accurate analysis.

(19) As a means of conducting a rapid investigation of a bent, the method of K-percentages is recommended by the Sub-Committee as particularly valuable. This routine procedure is based upon a consideration of the relative stiffnesses of the members of the frame from which the vertical wind reactions at all columns may be obtained with reasonable accuracy.

(20) Assurance of bent behavior in accordance with theoretical assumptions and deflections within desired limits can be had only when the bent is proportioned in accordance with the principles of elasticity. When the height-width ratio of a building exceeds about 5, a method of design, such as that of Spurr, which maintains planarity of floors under wind loads, should be used. Otherwise, proper provision for secondary stresses caused by the axial deformations of the columns should be made.

(21) Where high buildings have been proportioned without insuring regularity in the vertical movements of the successive floor joints, great complexity is introduced and an accurate analysis becomes a difficult and impracticable task. Unless a bent is so designed that the floor joints move in a predetermined manner, secondary wind moments will need to be computed after the primary direct wind stresses have been found in the columns. This may be accomplished by an application of the Cross method, but it involves a laborious procedure. On investigation, bents designed in accordance with the portal method may show large errors in girder shears in the upper portion of frames having a large height-width ratio. In buildings with setbacks provision must be made for unequal axial deformations of the columns.

(22) The effects of torsion should be investigated, particularly if the building is unsymmetrical in plan about an axis parallel to the direction of the wind. If the building is unsymmetrical about both axes, a wind from any direction may cause torsion. Although a solution sufficiently accurate for many purposes may be based upon the neglect of all deformations except girder bending, it is desirable to include the effect of axial length changes of the columns. Over-all economy is not served in any attempt to eliminate torsional moment by the stiffening of certain bents.

(23) Vibrational characteristics of buildings and the relation of sensation thereto must be determined experimentally before they can be designed with certainty to yield a desired degree of comfort to the occupants. Until such vibrational characteristics are more fully understood, it is recommended that the maximum computed deflection of the building at the top, when the structural frame is assumed to carry the entire lateral force, should not exceed 0.002 of the height.

(24) The Sub-Committee recommends that for members or details subject to wind stress only, except rivets and bolts, the permissible stress should be the same as that allowed for dead load or for dead load and live load.

For members subjected to stresses arising from the combined similar action of wind and other loads, and for rivets and bolts subject to wind stress, the wind stress up to 33⅓% of the other stresses may be neglected, the excess wind stress being considered as equivalent to an added live-load stress, provision being made for it at the basic working stress for dead load and live load only. Higher combined stresses may be acceptable in the columns of very tall buildings.

Members subject to a combination of wind, dead load, and live load, of course, should have a section not less than the section required for dead load and live load alone at the normal working stress.

(25) Members subject to both axial stress and bending should be proportioned for the combined effects in such a manner as to be consistent with the proportioning of members for axial stress only at the stresses permitted in recommendation (24). Formulas are submitted to insure this result. In no case should the section selected be less than that required for gravity load effects only.

(26) The Sub-Committee recommends that the axial tension due to wind load in the critical column should not be more than two thirds of the dead-load compression in the bottom story of the column, unless the columns are securely

anchored to the foundation by anchors proportioned at the permissible stress applicable to members carrying wind load only. The foundation should be adequate for 1½ times any uplift that may be imposed on it.

ACKNOWLEDGMENTS

The Sub-Committee wishes to express its thanks to many persons, and in particular to Mr. Spurr and Professor Large for assistance received in the course of the preparation of this Final Report.

IMPORTANT EVENTS, DEVELOPMENTS, AND TRENDS IN WATER SUPPLY ENGINEERING DURING THE DECADE ENDING WITH THE YEAR 1939

REPORT OF THE COMMITTEE ON WATER SUPPLY ENGINEERING OF THE SANITARY ENGINEERING DIVISION

At the request of the management of the Sanitary Engineering Division of the Society, the Committee on Water Supply Engineering of the Division undertook to make its current annual report on events, progress, and trends in water supply engineering cover the past decade instead of only the year. The Committee has done as much with this ambitious undertaking as the time of its members has permitted but recognizes that much interesting matter is not included.

The reports of previous years have included notes of important water supply projects currently in process of construction. Such reports were published in *Civil Engineering* for March, 1934, and April, 1935; and in *Proceedings* for December, 1934, April, 1935, March, 1936, April, 1937, March, 1938, and March, 1939. The present report lays particular emphasis on the progress and trends in water supply engineering.

The past decade has been peculiar in that it began with the great depression and lies entirely in the depression period. This depression is still continuing into the new decade although with some present abatement. The decade has witnessed the greatest government spending of all time. A full share of this spending has gone into water supply construction. The water supply engineering profession had an important part in advocating and encouraging this spending policy and has taken advantage of it. To some extent, however, private water utilities have offset the government spending on water supplies because their expenditures have had to be greatly decreased. The federal government's total expenditure in the decade has been more than $70,000,000,000 as compared with about $30,000,000,000 for the previous decade of great prosperity. Expenditures by private interests for capital goods decreased to $45,000,000,000 in the past decade as compared with $71,000,000,000 in the previous decade of great prosperity. The Committee has no exact statistics on the total expenditure for water supplies in the decade just passed as compared with the previous one, but is of the opinion that the total is greater than in the previous decade, although the engineering control of these expenditures has not always been so orthodox.

DROUGHTS, DRY WEATHER YIELDS, FLOODS, AND SPILLWAYS

At the beginning of the decade there was a very severe drought in the eastern and midwestern part of the United States. Again, from the spring of 1939 to the spring of 1940, drought conditions were severe.

As to floods, the past 10-yr period has brought floods of greater severity than any of those of the past century, and in some localities the floods have been of an intensity that probably occurs only once in several centuries. These floods have radically affected the design of spillways for dams, flood channels, flood protections for water works, and levee levels.

In New England, one of the areas in which long-time rainfall and runoff records are available is in the vicinity of Hartford, Conn. The rainfall record extends back to 1868, although the stream-flow records for the Nepaug and East Branch rivers start only with the year 1912.

In 1937, Caleb M. Saville, M. Am. Soc. C. E., stated[1] that from the Hartford record the maximum calendar-year rainfall occurred in 1920, amounting to 56.95 in. and that the minimum occurred in 1935, which totaled 28.90 in.

He stated that in this area the "great" flood came in March, 1935, on both the Farmington and Connecticut rivers. In the local watersheds, the runoff from the East Branch watershed of the Farmington River, with 62 sq miles and with 8.14 in. of rainfall from March 11 to noon, March 18, was equivalent to 11.7 in. with a peak runoff of 135 cu ft per sec per sq mile. In the Nepaug watershed of 32 sq miles, the corresponding figures for this time period were: Rainfall 6.95 in., runoff 8.8 in., and peak flow 98 cu ft per sec per sq mile. On November 2 to 4, 1927, with a rainfall of 6.52 in., a peak flow of 141.8 cu ft per sec per sq mile was recorded on the East Branch.

As a result of these and other lesser storms and studies of their flows, the new Barkhamsted (Conn.) Reservoir of the Hartford system, which has an earth dam, is designed for a peak flow of 500 cu ft per sec per sq mile. Mr. Saville explains that one reason for this large spillway capacity was that the additional cost for the large capacity was small. This reservoir is on the East Branch of the Farmington River at Barkhamsted; it has a drainage area of 52.7 sq miles and a capacity of 30,000,000,000 gal.

The Farmington River joins the Connecticut River 6 miles above Hartford with about 600 sq miles of watershed. The watershed of the Connecticut River at Hartford is estimated at 10,560 sq miles. The maximum flood-gage height in a period of 93 years previous to 1936 was 29.8 in 1854, while in March, 1936, it was 37.6 with a runoff of 28.4 cu ft per sec per sq mile as compared with 19.5 cu ft per sec per sq mile in 1854. Previous to 1936, the flood heights reached had a frequency estimated as once in 25 years, and in 1936 the flood height was estimated to be one that would occur once in 300 years.

[1] "New England Droughts and Floods in Their Relationship to Water Supply," by Caleb M. Saville, *Journal*, New England Water Works Assoc., Vol. 51 (1937), No. 3, pp. 326–366.

Comparison may be made with the heavy flood that occurred in November, 1927. This was much more severely felt in Vermont than in any of the other New England states. W. F. Uhl, M. Am. Soc. C. E., has stated[2] that the November, 1927, flood did $40,000,000 worth of damage, with two thirds in Vermont, and the 1936 flood did $70,000,000 worth of damage, with $55,000,000 in the Merrimack and Connecticut river valleys. In the 1927 flood, the runoff of areas of 20 and 40 sq miles reached 300 cu ft per sec per sq mile; for 200 sq miles, 200 cu ft per sec per sq mile; and for 1,000 sq miles, 114 cu ft per sec per sq mile. For the 1936 flood, the high runoffs for the small watersheds did not reach the maximum shown for 1927, but for 170 sq miles, 180 cu ft per sec per sq mile were shown. It was stated that the 1936 flood exceeded previous records for the greater part of New England. It was further stated that at Hartford the 1936 flood exceeded any for at least 150 years. In the Merrimack River, the flow of 1936 exceeded by 60% any floods in the previous 200 years.

It has been reported[3] that the summer flood of July, 1935, on small streams in New York State reached 2,000 cu ft per sec per sq mile for watersheds of 5 sq miles and less. For 100 sq miles, the flow was recorded up to 200 cu ft per sec per sq mile. The floods of March, 1936, showed lower flows, generally, than the 1935 flood.

On September 21, 1938, a hurricane swept over New England, and the rainfall exceeded previous records for large areas. The 16-in. fall covered 250 sq miles, a 14-in. fall covered 1,800 sq miles, and 6,600 sq miles had a 12-in. rain. With such precipitation, a flow of 175 cu ft per sec per sq mile came from the West River, Mass., compared with 127 cu ft per sec per sq mile in the November, 1927 storm. From a 178-sq-mile area on the Deerfield River, the recorded flow was 316 cu ft per sec per sq mile. On the small tributaries of this same river, flows of 700 cu ft per sec per sq mile were found for areas of 25 sq miles.

Special attention has been directed to the New England floods of November, 1927, March, 1936, and September, 1938, as in the short space of 12 years three major floods have visited this area, although the three floods did not set up maximum flows at exactly the same points in the New England area.

Pittsburgh, Pa., experienced its worst flood on record in March, 1936, when a crest of 46 ft was reached, compared with the previous crest of 35.5 ft, which represented the highest level for 86 floods that had occurred since 1856. The drainage areas of the Allegheny River and the Monongahela River at Pittsburgh total 18,900 sq miles.

The Ohio Valley flood of January, 1937, surpassed all previous floods that had occurred during the 175 years of the occupancy of the valley by white men. At Louisville, Ky., the runoff of the flood was estimated at 8 in. of rainfall, as against 6 in. for the 1884 flood which was the most severe flood that had been recorded previously; the flood level was 12 ft higher in January, 1937, than previously. It was estimated that the flood level was probably about 4 ft higher than it had been in the 1773 flood, which may have been of about equal volume to that of 1937.

[2] "Flood Conditions in New England," by W. F. Uhl, *Transactions*, Am. Soc. C. E., Vol. 103 (1938), pp. 578–612.

[3] "The New York Floods of 1935 and 1936," by Arthur W. Harrington, M. Am. Soc. C. E., and Hollister Johnson, Assoc. M. Am. Soc. C. E., *loc. cit.*, pp. 613–621.

In California, a very heavy flood which caused much damage occurred on December 9 to 12, 1937, and a 12-in. rainfall was reported for the Yosemite Valley.

In the Southern California area, a flood on March 2 to 5, 1938, caused much damage in the Los Angeles section. It is reported that the rainfall was as great as 30 in. in some of the watershed areas.

The drought in 1930–1931 in the Croton River watershed of the New York water supply system was not quite as severe as the drought of 1879–1883. The Croton River rainfall and runoff records have been continuous since 1868. The Croton system has a tributary watershed of 375 sq miles and a storage capacity of 103,000,000,000 gal. From 1911 to 1931, the estimated dependable supply from the Croton watershed was considered to be 335 mgd. As a result of the drought of 1930–1931, which really extended as a dry period from 1929 to 1932, engineers of the New York City (N.Y.) Water Department determined that 25% of the total storage should be considered as a special reserve, and that the dependable yield should be estimated only on the basis of utilizing 75% of the storage. This reduced the estimated dependable yield of the Croton watershed from 335 to 300 mgd.

In the Schoharie and Ashokan watersheds, which comprise the Catskill system and have a combined area of 571 sq miles, the record of rainfall and runoff is available from 1907. The dryest period on record in these watersheds occurred from May 1, 1930, to March 23, 1931. During this period, a draft of 601 mgd would have practically drained the main reservoir, which is the Ashokan Reservoir, holding 131,000,000,000 gal. Prior to this drought period, the Catskill system was operated on the basis of 585 mgd for dependable supply, utilizing the total storage available. After this drought of 1930–1931, 75% of the available storage was assumed to be available for maintaining draft, and the dependable yield was reduced from 585 to 500 mgd.

In the Hartford district, Mr. Saville reports that the maximum drought period was between 1879 and 1883, when, for 5 years, the average rainfall was 35.72 in. and the lowest year in that period was 33.64 in., or 77.1% of the average. For the 5 years beginning with 1931, the average was 39.66 in. which was the next lowest 5-yr average, with the 1935 rainfall of 28.90 in. only 66.2% of the average. Four very low 5-yr periods have been noted since 1836. Two have been mentioned already; the other two started respectively with 1845, averaging 39.70 in., and 1910, averaging 41.01 in. The 100-yr period was secured by using for 1836 to 1868 the Amherst, Mass., and Springfield, Mass., records, which are longer than the Hartford record, and these were interpolated for Hartford. This interpolation was made by developing the relationship between these three records for the years for which records are available at all three stations.

From 1874 to 1886, or thirteen consecutive years, the Hartford rainfall was below the average and averaged 40.40 in., or 7.4% below the long-time average. However, for a 2-yr period, the minimum was 1930–1931, averaging 34.94 in., or 80% of the average.

The lowest runoff, for twelve consecutive months recorded since 1912, into the Nepaug Reservoir of the Hartford system, with a tributary watershed of

32 sq miles, occurred from March, 1930, to February, 1931, the runoff being 9.43 in., or 41.9% of the average annual runoff. The lowest runoff for sixty consecutive months was from January, 1928, to December, 1932, when the runoff averaged 18.69 in. or 82.9% of the long-time average. For forty-eight of the sixty months the figures were, respectively, 15.41 in. and 68.5%.

As a result of these runoff records, with storage available of 9,540,000,000 gal and 32 sq miles of watershed, the working safe yield of Nepaug Reservoir was taken as 21 mgd.

Although the drought of 1930–1931 was approximately of the same severity as that of 50 years earlier, the effects of this drought in influencing the responsible engineers to decrease the estimated dependable yield of watersheds having rainfall and runoff records extending back some 70 years is the item of special interest to water supply and sanitary engineers.

During the past 10 years it is obvious that the trend has been toward making greater allowance for maximum floods and spillway capacity, and reducing the estimated dependable yield of watersheds, such action being brought about by the floods and droughts of this 10-yr period, viewed in the light of earlier records of rainfall and runoff.

EARTH DAMS

The earth dam has gained in importance and in engineering interest during the past decade. In height, and particularly in volume, the magnitudes of recently completed and proposed structures have set precedents. At present, a rolled-fill dam approximately 400 ft high is under construction on the White River in the State of Washington. The Fort Peck Dam on the Missouri River in Montana has an embankment volume of approximately 122,000,000 cu yd. In large measure, this expansion has been due to the federal program of public works construction.

Both the hydraulic and rolled-fill methods of construction continue to be used, the choice depending on the character of material available, the adaptability of equipment to local conditions, and the comparative resulting costs. In general, hydraulic fill construction is limited to projects of large volume because of the cost of plant installation; but the increased size, power, and speed of available transportation and compaction equipment have so reduced the comparative cost of rolled-fill construction that more than two thirds of the dams 100 ft or more in height, built during the past 10 years, have been constructed by this method.

The increased capacity of construction equipment is notable: 25-cu-yd trucks, 30-cu-yd scrapers, 8-cu-yd draglines, and dredges rated at 1,500 cu yd per hr are now obtainable. For compaction of rolled fills, the sheepsfoot roller, because of its greater concentration of deeper pressure and its ability to leave the surface loose and ready for the next layer, has become standard equipment. In hydraulic fill practice, belt conveyers have been used to lift and transport material from the borrow pit to the hog box, and rubber-lined pipe has been successfully employed in the delivery lines from pump to equipment. Booster pumps in the delivery lines have made it possible to carry material a distance of 5.0 miles in some cases.

As a result of these developments in equipment, the cost of earth fill in place has been reduced greatly, being now (1940) about two thirds of that prevailing 10 years ago. Present prices per cubic yard range between 30¢ and 50¢, and contracts, both in the rolled-fill and hydraulic methods, have been let at less than 20¢ per cu yd.

The rapidly developing science of soil mechanics has been responsible, in considerable measure, for the confidence necessary to the undertaking of the unprecedented magnitudes of recent structures. Beginning in the United States about 1925 with the work of Karl Terzaghi, M. Am. Soc. C. E., the intensive study of the physical properties of soils became quickly popular. As a result, a more rationalized design and better control in the construction of dams has been made possible. This has not prevented some partial failures, however, such as those at the Tappan Dam on the Muskingum River in Ohio, the Fort Peck Dam on the Missouri River, and the Marshall Creek Dam on Marshall Creek, Kansas.

As evidence of the increasing interest in the design of dams and soil mechanics, several notable conferences have been held, with published results, as follows:

1. *Proceedings*, First International Congress on Large Dams, Stockholm, 1933.
2. *Proceedings*, Second International Congress on Large Dams, Washington, D. C., 1936 (Supt. of Documents, 5 Volumes).
3. *Proceedings*, International Conference of Soil Mechanics, Harvard University, 1936, 3 Volumes.
4. *Proceedings*, Soils and Foundations Conference of the U. S. Eng. Dept., Boston, Mass., June 17–21, 1938—printed January, 1939.

The Soil Mechanics and Foundations Division of the Society was created in 1936, and this Division has prepared a manual[4] containing a list of some 300 publications on soil mechanics, many of which deal with the design of earth dams.

Soil testing laboratories are now generally provided for the continuous testing of borrow-pit material for size gradation, compaction under varying moisture contents, and for settlement and shearing strengths under load. Shear and permeability tests are made of "undisturbed" samples of the foundation material. As the fill progresses, other tests of undisturbed samples of the fill for gradation, weight, moisture content, compaction, and shear are made.

Lines of seepage have been studied in model dams between glass slides to indicate the probable flow net, and model tests of spillways and outlets are becoming customary. In some cases, a gelatin model loaded with shot has been used to forecast the shear zones.

On the basis of the information thus collected, the most dangerous line of failure in shear is derived, and the section of the embankment necessary to provide the desired factor of safety is determined. Settlement under load is forecast and the permissible rate of construction or application of load is controlled accordingly.

---

[4] "Selected Bibliography on Soil Mechanics," *Manual of Engineering Practice No. 18*. American Society of Civil Engineers.

A refinement of the embankment design has thus been made possible and such partial failures as have occurred point to the foundation material (through which the line of maximum shear may pass and the evaluation of which is dependent on the number and validity of so-called undisturbed samples) as the element of greatest risk. In any case, the factor of safety to be applied remains a matter of judgment.

The fundamental requirments of an earth dam are reasonable watertightness and permanent stability against sloughing when the material is saturated and subject to the effect of percolating water. Present-day design, therefore, generally includes a central impervious section and more or less pervious shells with the shearing strength necessary for stability. Masonry core walls are seldom used and even key walls to connect the earth fill with the rock are questioned, reliance against seepage through the embankment being placed on a section of selected soil. Provision is made for safe discharge of such seepage as may result by adequate drainage in the form of gravel or rock fills, with reversed filters at the toe or inside the lower downstream pervious section.

The most interesting and cost saving development in method of providing a subsurface cutoff is that of sinking concrete caissons after a preliminary lowering of the ground water. This method was used in the construction of the Quabbin Reservoir dike, and dam of the Metropolitan District Water Supply Commission of Boston, Mass., and is to be used in the Merriman Dam of the New York City supply. An increased confidence in the value of steel piling as a subsurface cutoff has been indicated.

A marked increase in the provision of spillway capacity has been a notable development of the past decade.

In summary, although there has been little change in the theory of design, laboratory and field tests of the physical properties of soils have made possible a more definitely quantitative design and have supplied a basis for better evaluation of future success or failure. It is not to be understood, however, that the laboratory has eliminated the need for engineering judgment founded on experience. The choice of a factor of safety for shearing of the fill and foundation, for example, is the crux of design and is always an act of purest judgment.

Trends in Design and Construction of Masonry Dams

During the past decade no substantially new form of dam has been constructed. (The Coolidge Dam, in Arizona, of the multiple-dome type, was practically completed in 1928.) Rather, the outstanding development has been the design and construction of the earlier-type dams to greater heights than ever before. Hoover Dam, in Nevada and Arizona, constructed from 1931 to 1935 and having a maximum over-all height of about 727 ft, is designed to raise the water level of the Colorado River about 578 ft, whereas Shasta Dam of the Central California Project has a maximum over-all height of about 550 ft, and is intended to raise the waters of the Sacramento River about 490 ft. The former is massive, involving both gravity and arch action; the latter is a curved gravity-type. The Shasta spillway, located in the center of the dam, will be the highest ever built. There is no demonstrated limitation against still greater heights of dams, given appropriate physical conditions of site.

Outstanding in another respect is the Parker arch dam of the Metropolitan Water District of Southern California, which, although it raises the water of the Colorado River, in California and Arizona, only about 105 ft, has a maximum over-all height of about 320 ft—that is, about two thirds of its maximum height is under the original river level.

In the design and construction of smaller dams, as well as of the larger dams such as the foregoing, changes and tendencies have evolved, the more important of which are mentioned, although by no means exhaustively, in the following statements:

Foundations.—Clearly in the decade 1930–1939 there has been a continuation of the previous tendency to explore, more extensively and carefully, Nature's materials in foundations and abutments. The normal tendency in this respect has been augmented by the fact that, many of the better dam sites already having been utilized, it is becoming more and more necessary to construct dams where foundation conditions are relatively inferior. Geophysical methods are used somewhat, particularly for preliminary exploration, but for final exploration, borings—especially core borings—are used. The desire for still more intimate knowledge of foundation and abutment conditions finds expression in shafts and tunnels and in core borings of sufficient diameter (30 in. and larger) to allow direct inspection.

Because of the fact that, in the main, failures of masonry dams have been by sliding, there is growing recognition of the need for caution where the foundation material is unconsolidated or involves approximately horizontal stratification, with shales receiving special attention. Low resistance against horizontal movement is remedied by tying the dam deeply into the foundation material—for example, by anchoring walls of concrete, an expedient that is hardly efficacious for dams as high as 200 ft. Fortunately, higher dams of masonry are rarely attempted upon foundations having such characteristics.

Consolidation by grouting of yielding or fissured rock forming the foundation or abutments of dams (practiced, for instance, at Norris and Claytor straight gravity dams, in Tennessee and Virginia, respectively, and at Shasta curved gravity dam) is becoming standard procedure. Consolidation generally is under the entire base of the dam, but particularly at the downstream portions. Abutments naturally receive intensified attention in this respect in the cases of arched dams.

Solution channels in limestone and dolomitic foundations, especially where there is much jointing or faulting, have resulted in extensive, deep pressure-grouting operations in the rock at the upstream faces of the dams in order to minimize underflow and uplift. Such grouting is being done to substantially greater depths and with substantially greater pressures than previously was common practice. Among the newer dams receiving such treatment are especially those in the carbonate-rock regions of the Appalachian Mountains, including Norris and Chickamauga dams of the Tennessee Valley Authority (TVA) on the Clinch and Tennessee rivers, respectively, and Claytor Dam on New River in Virginia, the latter being the largest dam built in the United States with private funds since the beginning of "the depression."

Earth foundations still limit substantially the heights of any dams founded upon them. However, it is recognized that within reasonable limits concrete dams, especially of the buttress type, may be constructed safely upon such foundations if adequate protection is provided against seepage under and around the dams and against scour at the foot of any spillway.

No longer is it taken for granted that a hard rock containing fissures or joints, or even only bedding planes, is immune from scour. There is greater use of concrete aprons and baffles to insure dissipation of the energy of the spillway discharge before it comes in contact with the stream bed. Scarcely any important spillway is constructed now without such special provision for prevention of scour. Inasmuch as the conditions of height of dam, depth of overflow, material in the river bed, and depth of tailwater are never alike at any two dams, the opportunity for empirical deductions from actual dams has been limited and there has been much recourse to model testing.

Temporary retention, in place, of unconsolidated material by means of freezing has been practiced, as, for example, at the Gilbertsville dam site of the TVA, around an exploration shaft, and at Grand Coulee Dam, in Washington, for preserving steeper-than-natural slopes around the foundation excavation.

Design.—Especially for the higher dams, analyses are directed to determination of the maximum (principal) stresses and not merely their horizontal and vertical components. As to considering a masonry dam as an elastic structure, there is practical unanimity, but not so as to assumptions, stated or tacit, that the elastic properties of a given dam or its foundation are uniform or fully known, or that the behavior of a high gravity dam having keyed and grouted longitudinal joints is in such respect actually that of a structure to which, as a monolithic whole, the theory of elasticity is applicable.

Likewise, there has been an increase in the extent and refinement of mathematical analyses. In the latter respect there are two schools, the one inclined to rely almost solely upon such analyses, the other tempering the use of the purely theoretical considerations by means of the empirical. Within the latter category there is included the use of tests of models, albeit with recognition of a lack of complete homogeneity in the prototypes and differences in behavior of the latter from that of small specimens of the actual materials of which a dam is to be built or upon which it is to be founded.

The special complication of stress determination in arch dams, involving as it does stresses in three directions, has been not merely the subject of various new theoretical approaches as to solution but has quite logically been the subject of extensive and refined model tests, as in the case of Hoover Dam.

It is recognized that foundation deformation affects stresses in the dam. For this reason, especially in the cases of some of the higher dams, such as Norris and Shasta, the angles between the faces of the dam and foundation are eased.

Although the analysis of resistance to sliding by considering shearing resistance or a combination of shearing and frictional resistances is substantially older than the last decade, yet that method, in contrast with the former reliance upon friction alone, has been used increasingly. Especially in cases where pressure-grouting has been done to establish at the upstream face practically complete cutoff against underseepage, and where relief drainage has been provided downstream from the cutoff, such physical provision and the results of such of the highly desirable tests of actual uplift pressure at dams as are available, have led to some degree of reliance upon the assumption that the uplift forces will be substantially less than under the common, older assumption of straight-line decrease from full headwater to tailwater pressure. In the cases of certain larger gravity dams there has been introduced, primarily by the designing force of the Bureau of Reclamation, analysis of the effect of "twist" as caused by transfer of load between adjoining monoliths and between the dam and the abutment rock. Indeed, in Grand Coulee Dam vertical slots are left to allow for adjustment in respect of twist; after adequate adjustment is believed to have taken place the slots are to be filled with concrete and grouted

More and more, in regions subject to earth movements, analyses are taking into account the increased stresses due to earthquakes. Where it is found necessary to locate masonry dams across faults, and where there are specific possibilities of movement at known faults, special expedients in design have been adopted to ameliorate the results of any such movement. Outstanding in this respect are the Morris gravity dam, in California, with its "open joint" and the buttress-type Rodriguez Dam, in Lower California, Mexico, with its footing arch over the fault zone and its tying together of pairs of buttresses in a "tower" construction to resist earthquake action.

There is increasing recognition that, in general, the maximum floods of record constitute only woefully inadequate measures of the maxima which may occur; the result is increased provision for flood discharge. On the other hand, with the recognition that such special earthquake stresses and maximum flood loadings will occur only rarely, if ever, it is not unusual to permit higher unit stresses therefor than for the normal maximum loads.

It has become general practice to provide gates on spillway crests in order to permit continuous utilization of the head (and the corresponding storage capacity) represented by the height of the gates. In consequence spillway gates have been constructed to greater heights than heretofore, and the desire to insure against clogging by debris has resulted in greater lengths of clear openings. Such surmounting of the aforementioned Parker arch dam with crest gates 50 ft high necessitated corresponding thickening of the arch ring at the spillway crest so as to allow the gates and their spillway piers to function by gravity action with the arch dam as foundation. Where topographic and stream flow conditions permit, however, the practice is to separate flood discharging facilities from the arch dam proper; this has been done at both the Owyhee (in Oregon) and the Hoover dams.

Marshall Ford gravity dam on the Colorado River of Texas, designed by the Bureau of Reclamation and completed as to its first stage in 1939, is unique in its provision for increase in height (from 190 ft to 268 ft) by additions only on the upstream side.

Construction of Dam Proper.—Although the use of portland-cement concrete, instead of stone masonry, is predominant, the infirmities of concrete receive great attention. Indeed, the Board of Water Supply of New York City, in general, builds exposed masonry surfaces of stone, not concrete.

Outstanding among the aims in present-day construction of masonry dams is improvement of the quality of the concrete—not its strength, which generally is ample, but its durability and water tightness. Wet concrete is outmoded; complete, but not excessive, vibration, as a necessity as well as a desideratum for the placing of the relatively dry concrete, is a fully accepted process. The primary effort has been to prevent cracking. To this end cements of lower heating characteristics have been developed, the most important early applications being at Morris and Hoover dams. Temperature control has been practiced also by embedding pipes in the concrete for circulating cooling water, as in the cases of the larger dams constructed under Bureau of Reclamation specifications, or by the precooling of mixing water or the aggregates themselves, as at Hiwassee Dam, in North Carolina. Decrease in height of lifts to about 4 ft, or even less at the foundations, and longer time intervals between placing of superimposed lifts have likewise been found helpful; indeed, the emphasis upon quality has resulted in definite restraint upon speed of construction.

For the purpose of preventing disintegration of concrete exposed to alternate freezing and thawing, and of obtaining greater resistance to seepage through the upstream concrete below reservoir level, there is continuance (for example, in the TVA construction) of the practice of placing richer concrete near the faces. As to this practice, however, there is not complete agreement, for there are those, competent to have opinions, who attach greater weight to the resultant lack of uniformity and to such disadvantage as there is in the richer concrete because of greater, thermally caused volume changes; consequently they advocate relatively lean concrete even for dam faces.

There is more nearly unanimity as to the feasibility of using lean mixtures (1 bbl or less per cu yd) for the interior masses, particularly where they are quite dry and thoroughly consolidated by vibration. Differences of view in this respect involve mainly the extent to which leanness may be carried. However, there are those, including the late Thaddeus Merriman, M. Am. Soc. C. E., who have subscribed rather to the view that, granting certain weaknesses of portland cement, including its thermal activity in early life, nevertheless there is no adequate substitute for plenty of good cement. There is a strong tendency to specify cement content in terms of water-cement ratio in addition to, or even without, minimum quantities of cement per cubic yard.

For any masonry dam regardless of height, the art recognizes that prevention of transverse (to the axis) cracking, not to mention the practical needs of construction, requires division of the structure into blocks by means of transverse joints. Distances between joints are commonly, and generally successfully, 40 ft to 50 ft, but, where crest-gate lengths dictate, the foregoing consideration may be overruled, as in the case of Claytor Dam, with its spacing, in the spillway section only, as high as 60 ft.

The need to avoid cracking had led to the practice, initiated on a large scale at Hoover Dam, of dividing the structure not only by transverse but also by longitudinal joints, likewise 40 to 50 ft apart. Such practice results in constructing a dam by blocks, with resultant need for uniting the blocks into monoliths. Engineers have sought to accomplish this by somewhat elaborate keying and later grouting of all such joints, as at Hoover, Grand Coulee, and

Shasta dams, where the intent has been to make a huge monolith of the entire dam, once the concrete has cooled to practically its ultimate temperature. Metal seals at such joints are provided to divide the grouting into predetermined sections.

As to arch dams, there is general agreement that transverse joints, properly grouted, insure the intended arch length and hence immediate arch action despite previous shrinkage of concrete. So far as is known, circumferential joints in arch dams (as used at Hoover Dam, for example) have not been criticized. However, as to huge dams dependent solely on gravity, it has been suggested that keying and grouting of joints parallel to the axis have not yet been demonstrated to result, in that respect, in elastic action and margin of safety equivalent to those of a monolith.

An alternative to such use of transverse contraction joints involves, in effect, expanding the joint so that it becomes a slot several feet wide, and, after normal temperature has been attained in the mass, filling the slot with concrete, without provision for grouting. Except for the cooling slot in Hoover Dam, this alternative appears to have found application only in Europe.

There is increasing recognition of the importance of the treatment of horizontal construction joints with the aims of providing adequate bond, or at least shearing resistance between successive lifts; of obviating disintegration at the exposed faces (in particular immediately below such joints); and of minimizing seepage along the joints, with its detrimental effect upon durability. The extreme instance of precaution in this respect is probably under the specifications for Claytor Dam, but great care is exercised under other specifications, including those of the Bureau of Reclamation. Sandblasting of the surfaces of horizontal joints is now (1940) practiced at Grand Coulee Dam and is commanding increasing attention elsewhere.

Buttress-Type Dams.—Much of the foregoing is pertinent also to so-called hollow dams, consisting of flat or arched decks supported by piers. The use of these structures has continued where need for economy in masonry has dictated, and also where there are anticipated differences, in foundation deformation or even fault movement, between different sections of a dam. In dams of this kind, as in the cases of gravity and single-arch dams, the past decade has witnessed the overtopping of previous heights. Thus, the flat-slab, Rodriguez Dam, with an over-all height of 250 ft, and the multiple-arch, Bartlett Dam, in Arizona, with an over-all height of about 286 ft, successively assumed first place.

The trend is toward wide spacing of buttresses. In this respect the Don Martin, roundhead, buttress-type dam, in Mexico, involved a spacing of 29.5 ft between centers of buttresses, being at least one third greater than previous buttress spacings for a flat-slab dam. The massive buttress of the Possum Kingdom flat-slab dam, in Texas, completed in 1940, has a spacing of 40 ft; but even this is a "far cry" from the 180 ft of the Coolidge multiple-dome dam, in Arizona, completed in 1928.

Records and Reports.—There is a distinct increase in effort to determine and record accurately the forces actually effective upon and within completed dams and the behaviors of structures, including the constituent concrete, under external and internal stresses. However, in this respect it is only the trend and not the total of accomplishment which is laudable.

The "Technical Report on Construction of Morris Dam," in 1935, sponsored by the Water Department of the City of Pasadena, Calif., set a fine example of recording for the use of the profession the history and much detail as to design and construction of that structure.

ROCK-FILL DAMS

Rock-fill dams, as a distinctive type of structure, had their origin in the mining regions of the Sierra Nevada of California. There they constituted a very logical solution of the local problem—provision of storage at remote locations, where transportation of material and equipment would have been costly, where sound rock in unlimited quantities constituted the most easily available material for construction, and where a very large portion of the local population was accustomed to the use of explosives in mining activities. The same type of structure has been used since elsewhere, where conditions were generally similar; it has been used also where yielding or movement of foundations was to be anticipated. In 1939, very complete information concerning rock-fill dams, from the earliest examples in the mining regions of California to the largest recent structures, was made available.[5]

In Mexico the low cost of labor and the high cost of imported equipment has led to the adoption of the rock-fill type for five important dams: Charcas Dam, State of Guanajuato, 1933, 49 ft high; Taxhimay Dam, State of Hidalgo, 1934, 137 ft high; Madero Dam, State of Hidalgo, 1938, 153 ft high; San Ildefonso Dam, State of Querétaro, 1938, 189 ft high; and Tepuxtepec Dam, State of Michoacán, 1934, 126.5 ft high. In regions of Sweden, within the Arctic Circle, where the cost of concrete would be very high on account of the remote location, rock-fills have been used. In Chile, the possibility of earthquake damage to other types of dams has led to the choice of the rock-fill type. In Algeria, difficult foundation conditions have led to the use of rock-fills rather than masonry or concrete dams.

Extent of Use.—However, rock-fill dams have not been used as widely as a number of other types of structure. For example, in California, which may be considered the home of the rock-fill type, only 6.6% of the 588 dams under state supervision on January 1, 1936, were rock-fill structures; 64.5% were earth-fill; and the remainder, 28.9%, were of concrete or masonry; about the same percentages were reported to apply to the 950, more or less, dams examined. In a list of sixty major dams in California, thirty-four were concrete or masonry, and twenty-six were embankment dams, including ten important rock-fill dams of heights varying from 122 to 320 ft. In a similar list[6] of 600 important dams in the world, there were 38 rock-fill dams of which 17 were built in the period from 1930 to 1938.

Rock-fill dams are conspicuously lacking in the extensive construction program of the Bureau of Reclamation, although earth dams with heavy rock blankets on the downstream faces are numerous. Published reports of the Bureau show that rock-fill designs (as well as others) were considered, but discarded for the types shown, for the following structures: Stony Gorge Dam, Ambursen type, 142 ft high, 1928; Bartlett Dam, multiple arch, 270 ft high, 1939; and Deadwood Dam (in Idaho), concrete arch, 165 ft high, 1931. Although these are the only published cases of rock-fill dams having been discarded by the Bureau of Reclamation after comparison with other designs, it is possible that there are others.

---

[5] "The Design of Rock-Fill Dams," by J. D. Galloway, M. Am. Soc. C. E. (and the accompanying discussions), *Transactions*, Am. Soc. C. E., Vol. 104 (1939), pp. 1–92.

[6] "Dam Building Reaches a Climax," by Robert A. Sutherland, Assoc. M. Am. Soc. C. E., *Engineering News-Record*, December 10, 1936, p. 807.

Salt Springs Dam, in California, completed in 1930, still remains the highest purely rock-fill structure in existence. However, its height (313 ft above stream bed) has been exceeded by San Gabriel No. 1, in California, a rock-fill with an impervious earth-fill section.

Trends in Design.—Rock-fill dams vary widely in design. As a definite starting point in a discussion of these variations, the typical rock-fill structure may be taken as "A loose rock-fill forming the mass of the dam; an impervious face next to the water; and a rubble cushion between the two." Adequate design usually centers in two problems:

(1) Constructing the fill in such a manner as will cause the major portion of the total settlement to take place during construction and before placing of the watertight facing; and

(2) The selection of a type of facing that is sufficiently strong to withstand such loads as may come upon it and at the same time is flexible enough to follow without extensive cracking or fracture such residual settlement as may later occur in the fill.

The difficulties that have arisen in the solution of these problems under the differing conditions at various sites have led to modifications of the primitive or pure type of rock-fill, and these modifications appear to fall into two general groups:

(1) The substitution of dry rubble in place of the loose rock-fill, or (as the latter is often termed in California) the "drop-fill" section, forming the main portion of the dam; this substitution varies in extent, in some cases being only a moderate thickening of the dry-laid rubble cushion. In extreme cases a complete dry-rubble fill is substituted for the "drop-fill."

(2) Abandonment of the thin impervious facing of the dam (usually of reinforced concrete) and the adoption of a modified section in which the body of the dam is of rock-fill of various classes, and watertightness is secured either by an impervious earth blanket on the upstream side of the rock-fill, or an impervious earth core either in the upstream half of the dam, or as a central core of varying width.

The most complete change under group (1) is to be found in certain of the Algerian rock-fill dams, in the Shing Mun Dam (China), and in the Tepuxtepec Dam (Mexico); the most complete change under group (2) is to be found in the revised design of San Gabriel No. 1, and certain later dams.

In the United States, a large part of the knowledge of the behavior of rock-fill dams and the methods necessary for proper construction of the fill and design of facing has been derived from several very large structures, among them the Dix River, Salt Springs, Bucks Creek, and the two San Gabriel dams, in California. The latter are of particular importance in their apparent influence on subsequent designs.

Both of the San Gabriel dams were originally designed as typical rock-fills. Construction of Dam. No. 2 was started in July, 1932, and proceeded steadily until early in 1934 when it was interrupted on account of settlement that resulted from the heavy rains in December, 1933, and January, 1934 (and that reached as much as 12 ft vertically), wrecking much of the laminated concrete facing. This serious trouble served to focus the attention of all designers on the inherent difficulties in providing a type of facing satisfactory for very large structures, and on the care needed to reduce to a minimum the shrinkage in the fill.

At the same time, by coincidence, troubles of another type developed at San Gabriel Dam No. 1; there, prohibitive costs were resulting from the very great excess of quarry waste. This led to a change in the design of San Gabriel Dam No. 1 to a rock-fill with impervious earth section, which served not only to utilize quarry waste, but also eliminated concrete facing that would have been required with the rock-fill design, and with it went such troubles as had been encountered at San Gabriel Dam No. 2.

The precedent (of eliminating facing and substituting a section of impervious fill) set in the redesign of San Gabriel Dam No. 1 appears to have "carried weight," for since that time several dams consisting principally of rock-fill, but with impervious earth sections instead of facing, have been designed or constructed, and a continuous transition can be traced from typical rock-fills to earth-fills, with little difference between any two succeeding designs.

Progress in Knowledge of Ground Water

The past decade has been notable for a considerable increase in knowledge of ground water and in the inauguration of systematic surveys for the further increase of knowledge. Much of the information has concerned the limitations and exhaustion of ground-water sources. Extensive investigations were made of the ground-water levels and salt content on Long Island, N. Y., by private utilities and by the City of New York, followed by more extensive and continuing investigations by the state, national, and county governments. These emphasized the fact, previously known only to a few, that the western end of Long Island was already overpumped, with resulting increase in salinity. Since this fact became known, the state authorities have disapproved practically all applications for wells on western Long Island—that is, in Kings County and parts of Queens County of New York City, except for use in tight, noncorrosive cooling systems, in which cases wells for returning the water to the ground are required. Heating of the ground water has occurred in some of these cases where wells were too close together.

Immediate influence in ground-water levels between wells more than 10 miles apart in the water-bearing stratum called Lloyds gravel next above the rock on Long Island has been noted by systematic observations of the water levels. Pumping at one well results in decreased levels at distant wells.

Joint state and national investigations in New Jersey have disclosed salt intrusion caused by overpumping of wells in areas along the Raritan and South rivers.

Texas, particularly regions supplying the City of Houston, has been studied intensively, overpumping has been found, and increase in salinity noted. The region of Miami, Fla., has suffered salt intrusion caused by drought and reduction of water storage in the Everglades by too much drainage. A joint investigation by several agencies has been inaugurated.

In California, where ground water is still the lifeblood of the fruit, nut, and vegetable culture which forms the principal business of the state, the closest attention continues to be paid to ground-water levels and to the legal rights of persons using existing wells or projecting new wells. The irrigation or spreading of water on sandy and gravelly stream beds by the aid of a series of low retaining dams, to increase the yield of wells, has been practiced successfully, especially in the San Gabriel Valley south of Los Angeles. Two large dams, San Gabriel Nos. 1 and 2, for conserving flood flows for subsequent irrigation, have been constructed there in recent years.

In many parts of the United States ground-water investigations have been made because of the increased importance of the ground-water reservoirs in periods of drought which have occurred with unusual intensity in many parts of the country during the past decade.

The great advance in the scientific approach to the subject of ground water will be evident from the following enumeration of items of progress, description of which cannot be encompassed in the space available for this summary:

1. Establishment of a section on hydrology, of the American Geophysical Union. Valuable contributions to ground-water information are contained in reports of the Committee on Underground Waters for each of the years 1932 to 1939 inclusive, published in the *Transactions* of the Union for those years.

2. Establishment of a number of hydrological laboratories for the specific purpose of conducting research on the water-bearing characteristics of soil and rock.

3. Expansion in establishment of state well-drillers associations with consequent improvement in logs of wells and in preserving other valuable data.

4. Beginning in 1936, of annual publications by the U. S. Geological Survey of reports entitled "Water Levels and Artesian Pressure in Observation Wells in the United States."

5. Study of ground water by oil companies in connection with disposal of oil-field waters.

6. Development of a method of estimating the quantity of ground water available in an area, based on discharge by plants and evaporation from the soil. This was in the ground-water study in Escolante Valley, Utah (see U. S. Geological Survey, *Water Supply Paper No. 659a*).

7. Recognition of the existence of pollution by salt water and wastage of ground water by corrosion of well casings, and ways to correct the conditions in the Hawaiian Islands, New Mexico, Florida, and Texas (U. S. Geological Survey, *Water Supply Paper No. 796a*). Similar work has been done in California.

8. Discovery that yields from certain aquifers have come from stored water and not from recharge to the aquifer in the outcrop area. Such withdrawal of water has been accompanied by the compression of the aquifer.

9. General use of automatic water-stage recorders at selected inactive wells in areas under investigation.

10. Collateral-ground water studies made in connection with soil erosion studies and the attempt to reduce runoff (U. S. Geological Survey, *Water Supply Paper No. 679a*).

11. Better understanding of the "skimming process" for safely obtaining fresh ground water in regions subject to sea-water encroachment.

12. Use of geophysical method originally designed for use in prospecting for oil but also used for locating buried pre-glacial valleys containing ground water. The so-called resistivity method has been used in Texas and the Hawaiian Islands for determining the depth at which salt water will be encountered.

Among the recent valuable publications on ground water are a treatise by C. F. Tolman entitled "Ground Water" and a volume by Morris Muskat entitled "The Flow of Homogeneous Fluids Through Porous Media."

A device called a water mine, consisting essentially of a caisson from which horizontal wells in star formation are driven out sometimes to a distance of more than 200 ft, has been used successfully in Portugal, and also near the Thames River in England and in Ohio.

Graveled wells are being used increasingly, although wells adapted to the peculiar conditions, such as the California stovepipe well in which the casing is perforated after the well has been placed, continue to be used. There is an increasing use of brass and other copper alloys instead of iron or steel for screens both of the perforated-plate and the wire-wound types. Deep-well pumps instead of suction pumps are increasingly used, partly from prudence owing to uncertainty as to when the ground water will recede below the depth possible for suction; increased efficiency of turbine pumps have hastened this tendency. There is a steady increase in the use of turbine well-pump units with submersible electric motors directly connected below the pump.

AQUEDUCTS, TUNNELS, AND LARGE TRANSMISSION MAINS

The past decade has witnessed the construction of some of the most important aqueduct, tunnel, and large transmission pipe-line systems thus far constructed in the United States, including such mammoth undertakings as the 250-mile tunnel and conduit construction of the Metropolitan Water District of Southern California bringing water from the Colorado River to the Los Angeles metropolitan area and the 85-mile tunnel of the New York City water supply to make available 540 mgd from the Delaware River and Rondout Creek.

The work of the Metropolitan Water District of Southern California, in addition to the 250 miles of main aqueduct, includes about 140 miles of large branches. Of this total of nearly 400 miles, 92 miles were in tunnel. The conduit included some of the largest reinforced-concrete pipe thus far built, much of it being in sizes of from 9 ft to 12 ft 8 in. in diameter and designed for heads up to 285 ft. The making, transporting, and placing of pipe of this size necessitated the adoption of construction methods developed especially for the job and the terrain through which it passed.

The Delaware River aqueduct being constructed to supply New York City involves an 85-mile tunnel varying in diameter from 13.5 ft to 19.5 ft. This tunnel is of the deep-pressure type throughout its length, being located from 300 to 1,000 ft below the ground surface. Its construction involves 31 shafts, the length of the shafts alone exceeding 3.5 miles if placed end to end. Increased speed of construction has been notable in all this work.

Materials Used in Large Conduit Construction.—In general there has been a tendency toward the adoption of reinforced concrete or welded steel in large pipe construction. The use of cast iron has been less common than in former decades. However, there are a few notable exceptions, particularly since the availability of the new cast-iron-pipe specifications developed by Sectional Committee A21, American Standards Association (A.S.A.) (Sectional Committee on Specifications for Cast Iron Pipe and Fittings).

A review of recent literature covering approximately 600 miles of large conduit construction (36 in. and larger) indicated that approximately 40% were constructed of steel; 40% of reinforced concrete, with or without a steel cylinder embedded; and 20% of cast iron.

Reinforced-Concrete Pipe.—The first shop-built reinforced-concrete pipe of large diameter used in the United States was that at Baltimore, Md., about 1914. A recent examination showed this to be in an excellent state of preservation with its interior surface practically unimpaired in smoothness. From 1914 until 1930 approximately 225 miles of reinforced-concrete pipe in sizes 24 in. and more have been laid. In the decade between 1930 and 1940 an additional 380 miles have been laid. In other words, there has been 160% as much large concrete pipe laid since 1930 as in the 15 years prior to that year. This decade has also witnessed the use of reinforced-concrete pipe in larger sizes, up to 12 ft 8 in. in diameter, and under heavier heads than previously. The 54 in. crosstown Denver (Colo.) line operates under a 400-ft static head.

The earlier reinforced-concrete, pipe-line joints were of the jute-filled lead gasket type. In recent lines this is being superseded to a considerable extent by a rubber gasket type of joint. In this joint the rubber gasket is placed in a recess of the steel joint ring on the spigot end of the pipe. The shape of the steel joint ring on the bell end of the pipe is such that as the pipe is pulled home the rubber is compressed. The space inside and outside between the spigot and bell ends of the pipe is then filled with cement mortar in the same way as with the jute-filled lead gasket type of joint previously used.

One of the principal advantages of the rubber ring joint is that all calking is eliminated. Surrounded by cement-protected metal and thus protected from its chief enemies, light and air, the rubber is expected to have an indefinite life. Considerable evidence exists as to its durability under similar conditions.

Flow tests of reinforced-concrete pipe indicate little reduction of carrying capacity with age. An 18-yr-old reinforced-concrete pipe in Denver has still its original Williams-Hazen coefficient of 147.

Steel Pipe.—Practically all steel pipe lines in recent years have been of welded construction, thus eliminating the rough interior caused by laps and rivets and the longitudinal ridges of lock-bar construction and, in conjunction with improved linings, materially increasing the carrying capacity. Large steel pipe lines are now commonly made up in the shop in sections of from 30 ft to 40 ft—generally the latter and occasionally longer—the upper limit being determined by the necessities of railroad transportation and ability to follow the curvature of the railroad. Field joints are usually either welded, bell-and-spigot, slip joint (in which the bell is made by expanding one end of the pipe or by welding on a collar, the joint being made up by welding or by riveting and calking), or Dresser coupled. Probably a combination of the first and last named types of joint is used most frequently.

Standard specifications for lock-bar, riveted, and welded steel pipe 30 in. and larger have been developed by a committee of the American Water Works Association (A.W.W.A.) and are now (1940) under discussion. Specifications for smaller steel pipe, and for linings and external coverings of tar enamel and cement mortar, are well advanced.

Cast-Iron Pipe.—The use of cast-iron pipe in large sizes is receiving renewed attention since the standard specifications by Sectional Committee A21 have been made available. These specifications, which have resulted from 13 years of testing, research, and study by a Sectional Committee (A21) organized under the American Standards Association and sponsored by the American Gas Association, American Society for Testing Materials, American Water Works Association, and New England Water Works Association, have devised methods of design which take account of earth and truck loads as well as internal pressures. The adoption of spinning or centrifugal production methods for pipes of large size has made rapid strides and at the present time sizes up to 48 in. in diameter are being produced thus. Centrifugally cast pipe designed according to the procedure developed by Sectional Committee A21 was accepted for 81,000 ft of 30-in. pipe line at Corpus Christi, Tex., 121,000 ft of 30-in. pipe line at Greenville, S. C., and approximately 25,000 tons at Wichita, Kans., largely 42 in. and 48 in. in diameter.

Specifications for Purchase.—It has been quite common practice in recent years, on large conduits, to issue specifications designed to secure competition from two or all three of the aforementioned materials. Usually these specifications include bases of evaluation by which carrying capacity, probable life, and leakage, as well as fixed charges on the cost, are given consideration. There has been considerable variation in the bases of evaluation, depending upon the background of experience of the designer, the character of the soil as affecting exterior corrosion and of the water as affecting the interior, the maintenance of carrying capacity, and life. Officials of the Public Works Administration (PWA) have taken a hand in fixing these bases of evaluation on projects in which the federal government was providing a grant in aid. In a relatively few projects the only consideration has been that of price. "Protection from corrosion" is treated subsequently, covering both transmission and distribution mains.

TRENDS IN THE DESIGN AND CONSTRUCTION OF DISTRIBUTION SYSTEMS

Pipe Materials.—Cast iron continues to be the predominant material for the construction of distribution systems. The processes for producing cast-iron pipe have been greatly improved, resulting in greater uniformity in thickness and in metal strength. The process for centrifugal casting in metal molds without cores was introduced into the United States about 1922. The method of centrifugal casting in sand molds without cores dates from 1926, and pipe horizontally cast in green sand, with multiple gates, from 1922. Previous to this all cast-iron pipe was cast vertically in pits. At present only a small percentage of pipe is cast in pits and that is mostly in large sizes. Within the past 3 years (1937–1939) the centrifugal methods have encroached rapidly on the large pipe field.

Cement asbestos pipe was introduced from Italy in 1930. It has been produced there since 1916. It is now available from a number of factories distributed over the United States in sizes from 4 in. to 20 in., inclusive, and its use is increasing.

Steel pipe, with the various protective coatings mentioned elsewhere, has regained some of its former popularity. The cycle through which steel pipe for distribution systems has passed is an interesting one. In the middle and latter part of the last century it was used extensively in the eastern part of the United States in riveted form with thin plates and with a thick inner lining of natural cement mortar and often an outer mortar coating also. During the first quarter of the present century it was common practice for the more promotional type of developer in California, and perhaps some other states, to use thin riveted steel pipe in all sizes, using metal of 12, 14, and even 16, gage. No mortar protection was used but the surface protection was usually an ordinary hot asphalt dip, and lengths were joined by driving a tapered end into the preceding length after heating the coating so that it would seal the joint. Several miles of 9-in. and 11-in. riveted pipe, 16-gage thickness, laid in 1873 and 1876, have just been replaced in one California city because of a change in system operation involving increased pressures.

Then, for a time, perhaps due to an easier market in cast iron, little was done to advance the use of steel pipe in the distribution network although larger steel pipe, generally of substantial thickness, was used extensively for transmission lines. Recently, welded steel pipe with comparatively thin steel and tar enamel coating has been used to a considerable extent in competition with cast-iron and cement-asbestos pipe.

Now has come, particularly on the Pacific Coast, a further development of steel pipe, somewhat after the fashion of the cement-lined and covered pipe of the past century but applying the improvements afforded by the development of spun cement lining on the inside and reinforced gunite protection outside. The steel is much thinner than would be considered now for an all-steel pipe of the same diameter, being designed for the bursting stress with a minimum thickness dictated by experience to produce a pipe stiff enough to hold its shape during the spinning process. After spinning and guniting, the pipe can be handled safely, hauled by placing in cradles on truck or car, and laid with a stiffleg and sling. The normal thickness of lining on the Pacific Coast is about

½ in. and of gunite exterior about ¾ in. with mesh reinforcing. The pipe is welded and may be rolled from rectangular plates or spirally, from a strip. The joint between lengths may be of the bell-and-spigot design, calked with cement, and finished with mortar both inside and out. The steel is completely protected. For California, pipe of this design becomes cheaper than cast iron at approximately 16-in. diameter. For eastern United States the division point is at a somewhat larger size.

Methods of Laying.—There is undoubtedly a trend toward better laying methods designed to give the pipe the best chance, and the work of A.S.A. Sectional Committee A21 is undoubtedly responsible for some of this improvement. Doubtless many engineers have been astonished to learn to what extent pipe laid on blocks is more likely to fail and the strengthening which may be accomplished by tamping beneath and on the haunches of the pipe. More attention will be paid to these things in the future. For given conditions and factor of safety the additional cost of tamping is more than saved in the price of the pipe.

The Committee's elaborate work which has extended over 13 years has resulted in agreement among its membership, composed of manufacturers and engineers, on a revised method of getting at the design of cast-iron pipe barrels which takes into account not only the internal pressure but the external loading and manner of laying as well. This method is backed by a tremendous amount of data, either the result of experiments directed by the Committee or the work of earlier investigators. As a result of this work pipe can be designed for various pressures, various depths of cover, and different soils or laying conditions with a uniform factor of safety.

Joints.—The most notable trend in joints is the continued effort to depart from the use of lead.

Several lead substitutes have been used to a considerable extent and joints of neat portland cement have been found economical and very satisfactory. Lead joints are sometimes placed at intervals to provide a certain amount of ductility to the line. With improvement in the manufacture of rubber, rings of this material are being used with a follower for making up bell-and-spigot joints. Past history as to durability of rubber gaskets in enclosed locations is reassuring. Rubber also has the advantage of being easily sterilized.

Braided hemp for packing has shown economy over the old-fashioned yarn because of the saving in time. Proper lengths for a given size of pipe can be cut quickly and accurately, resulting in uniform joints and saving of material. It has been found to give less difficulty in sterilization of the line than loose jute which sometimes protrudes into the pipe and apparently acts as a culture for bacteria, probably harmless but giving undesirable laboratory reactions and proving extremely virile in resistance to chlorin. Main laying specifications show a tendency to be more stringent as to leakage than formerly.

Services.—During the past decade there has been a great advance in the design of services. The lead service is very much less used than formerly. Galvanized steel or wrought iron is still used, but a large number of communities have abandoned this material in favor of copper tubing which is now available at a reasonable price. Copper offers the advantages of resistance to corrosion;

flexibility, requiring no fittings to change direction for the purpose of changing elevation or passing an obstacle; and, since it comes in 60-ft lengths, requiring no coupling for any reasonable length. Up to this time no important drawbacks to its use have appeared, although there have been a very few reports of brittleness and there is an occasional report of green stains of origin as yet undetermined—possibly stray currents, possibly electrolytic action between dissimilar metals. Copper fittings are available for use with the tubing, either requiring expanding the end of the tube or the so-called streamline type which are soldered in place. With all copper from main to meter, the service may be considered as of equal permanence to any other part of the system.

Cement-lined steel pipe and fittings are also available in greatly improved form and are preferred over copper by some engineers. At the present time the cost is somewhat less. Cement-lined cast iron is available in sizes of 1½ in. and more, and is standard practice in many localities for larger services.

Valves and Hydrants.—No great advances or new ideas are to be noted in the design of valves and hydrants.

The A.W.W.A. has issued a new set of specifications which is intended to produce a more standardized valve.

Fittings.—Sectional Committee A21, in addition to its work on cast-iron pipe, also inaugurated some work on the design of fittings. Tests for strength and also tests for friction losses have been made. For fittings 12 in. in diameter, and smaller, a short body standard has been devised and is being used to a considerable extent as are other short body designs made by various manufacturers as standards of their own. For larger fittings no changes have as yet been decided upon, but the strength tests have indicated need for strengthening certain of the old standard designs in tees, crosses, and wyes having outlets the same or nearly the same as the main pipe, thus producing large flat surfaces at junctions of branch and main passages. Such fittings, though listed with certain pressure ratings, have seldom been used at those ratings and are not properly so rated.

PROTECTION OF PIPE LINES

There has been an increasing interest during the past decade in the phenomenon of decreased capacity of pipe lines caused by corrosion and tuberculation. Several outstanding reports have been contributed by committees of technical societies listing a very large number of flow-coefficient determinations that show, almost invariably, large reductions in carrying capacity. Tar dip had begun to yield to improved linings as much as 30 years ago, and a strong impetus was given to this movement in the decade previous to that included in this report by the introduction of spun cement linings in cast-iron and subsequently in steel pipe. The progress was slow, however, and water supply superintendents and engineers were seemingly less enterprising than their predecessors of 50 to 70 years ago, who laid many miles of thin steel pipe lined with natural cement mortar of very substantial thickness. None of this pipe has been reported as having deteriorated materially as regards its lining, although most of it has been retired on account of structural weakness.

As late as the report of this committee[7] for the year 1938, the cast-iron pipe lined with cement or other improved protection did not exceed about 10% or 12%, as reported to the committee, and as late as 1936 the value[8] was only about 7%. A recent canvass made by the manufacturers, for the Committee, indicates that the percentage has increased to about 29. This increase is caused largely by the development of a thin, spun cement lining, which is at first thoroughly rubbed on to the iron with the pipe spinning at low speed and then smoothed centrifugally by a higher speed. The thickness varies from $\frac{1}{16}$ in. for smaller sizes to $\frac{1}{8}$ in. for larger sizes. It is frequently protected from rapid leaching by a spray coat of asphalt.

For steel pipe in the East, spun tar enamel has continued to be the rule except for spun cement lining in stock-welded steel pipe in diameters of 25 in. and smaller. Tar enamel has been used extensively on the Pacific Coast, but the East Bay Municipal District and the City of Los Angeles appear to have standardized during the past few years on spun cement lining for steel pipe with reinforced gunite exterior coating. The City of San Francisco, Calif., has installed steel pipe coated with tar enamel without the usual priming coat. It is becoming the almost invariable custom to sandblast or steel shot blast steel pipe before coating; and also to whitewash the exterior coating where tar enamel is used to protect both interior and exterior enamel from the heat of the sun. Such whitewash has been found to improve the resistance of the coating to soil stresses. Tar enamel of improved quality, "plasticized," has come into use during the past decade. The laboratory methods of testing the primer and the enamel have become highly developed as have also methods of testing the enamel for pin-holes both in shop and field by high potential electric current.

Lining of Large Pipe in Place.—During the decade, a machine for applying cement mortar to large pipe lines in place by a centrifugal thrower followed by revolving trowels, has been developed and used for the lining with cement mortar of about 63,000 lin ft of steel main from 48 in. to 54 in. in diameter. It is understood that a greater amount is on order, indicating increased future use of this method. Most of the installations have been in the reconditioning of old pipes, but new work will include the lining of pipes laid without lining and then to be lined in place by this process. Linings are generally $\frac{3}{16}$ in. or $\frac{1}{4}$ in. in thickness. The process consists of dashing cement mortar on the interior of the pipe by a traveling machine containing essentially a centrifuge for throwing the mortar and a set of trowels attached to revolving arms which smooth the lining.

One who is acquainted with the development and practice during the past 15 years in the lining of cast-iron pipe with cement mortar, centrifugally, and with the developments of cement mortar lining of steel pipe on the Pacific Coast during the past 5 years, cannot but be struck by the extreme differences in the proportions and thicknesses of the linings and in the details of workmanship. The cast-iron pipe linings began with a mortar having three parts cement to one part sand, and in only a few cases, as far as the Committee is aware, has any mortar less rich than 1 : 1 been used. The early spun linings for cast-iron pipe were, in some cases, as thin as $\frac{1}{16}$ in., and the recently adopted A.S.A. standard provides for not less than $\frac{1}{8}$ in. thickness for the small pipe, $\frac{3}{16}$ in. for the intermediate sizes, and $\frac{1}{4}$ in. for the larger sizes. A few consumers have specified thicker linings but have been content with an increase of $\frac{1}{16}$ in. or so because of the manufacturers' fear of cracking or separation.

---

[7] *Proceedings*, Am. Soc. C. E., March, 1939, p. 429.

[8] *Loc. cit.*, April, 1937, p. 693.

The cement lining that has been responsible during 1939 for the great increase from about 12% to nearly 30% in the percentage of cast-iron pipe which is cement lined was described previously herein as having a thickness of $\frac{1}{16}$ in. to $\frac{1}{8}$ in., according to the size of the pipe. This lining is supplied without extra charge as compared with tar dip and, therefore, has been accepted by many who do not feel moved to pay for a cement lining of standard thickness.

In steel pipe on the Pacific Coast, linings of about $\frac{1}{2}$ in. average thickness are specified with limits of $\frac{3}{8}$ in. to $\frac{5}{8}$ in., or $\frac{3}{8}$ in. to $\frac{3}{4}$ in., and with mortar having proportions of 1 cement to $2\frac{1}{2}$ sand with even 1 part to 3 parts permitted in some cases. This latter proportion is, roughly, nine times as lean as the mortar that was commonly used in cast-iron pipe during the greater part of the past decade. In some cases, also, the steel pipe specifications provide for removal of laitance from the interior of the lining after spinning and its replacement with a surface finish of troweled mortar.

Some have recognized the importance of the choice of a proper cement for the lining of pipe, and the laboratories of several producers have investigated this matter; some of them are still investigating. The engineering profession has been very backward in attacking this question as a research matter. Obviously, a thin lining can be successful over a considerable period of time only if the cement is of very low solubility, and even a thick lining will lose its smoothness, with the resulting decreased carrying capacity, if the surface mortar becomes roughened by loss of cement. The favorable long-time experience with cement-lined steel pipe of the past century is unfortunately not directly applicable because it was done with natural, not portland cement.

Eastern manufacturers of steel pipe appear to be uncertain as to the safety of spinning a cement lining and subjecting it to the distortions caused by backfilling. As far as the Committee is aware, the western steel pipe lined with cement has been all covered with reinforced gunite and there is speculation (as yet unanswered by the test of construction and use) as to whether mortar lining in a large steel pipe not covered with gunite would be damaged by backfill even if the pipe, while being backfilled, were subjected to water pressure. The attachment of stiffening angles, or the use of special plates rolled with stiffening ribs, has been canvassed, but the expense involved renders this type of construction uneconomical as compared with other available types.

Lining of Small Pipe in Place.—During the past decade the Australian method of lining small pipe in place after cleaning it has been developed and is in extensive use in Australia, New Zealand, South Africa, and England. A recent beginning has been made in South America and the United States. The Committee is informed that in this country the method has been used in Pennsylvania, Massachusetts, and South Carolina and is about to be used in Florida and elsewhere.

Exterior Coatings for Pipe.—For the exterior protection of cast-iron water pipe, coal tar dip and, for cement-lined cast-iron pipe, various kinds of bituminous varnish as well as tar dip, are the prevailing methods of protection. For salt water and other corrosive conditions, tar enamel put on either over tar dip or over a special primer is frequently used, following the successful experience inaugurated about 25 years ago. In recent months cement mortar about ¾ in. or more thick, wrapped on with an open-mesh cotton fabric which is subsequently brushed over with mortar, has been used in some cases on pipe exposed to severe corrosion, as in salt muck.

On the Pacific Coast a process has been developed recently by which a mixture of bituminous filler with graded gravel and asbestos is fed hot, under pressure, to the exterior of a pipe which is mounted in a machine, so that the pipe comes out with a protective material having a thickness of ⅜ in. to ½ in. This development is made for oil pipes but is being applied under license.

During the last decade, the exterior protection of steel pipe used in water supply has been either of tar enamel or tar enamel with asbestos felt or kraft paper wrapping, or of gunite. One large job had a wrapped mortar covering. Reference has already been made to the East Bay Municipal District and the Los Angeles standard construction of mortar lining and reinforced gunite exterior coating for steel pipe. In very corrosive ground this gunite is placed over tar enamel on the exterior of steel pipe.

Cathodic Protection for Pipe Lines.—For some years well-informed water supply engineers have been watching the rapid development for the protection of gas and oil lines by the cathodic protection method. One long steel water main on the west coast (the Mokelumne pipe line of the East Bay Municipal District), following a partial failure of the bituminous and felt wrapping coating originally provided, has been equipped with cathodic protection. A recent specification for a long water main provided for a tar enamel coating and for the removal of stones and muck from backfilling to be used within 6 in. of the pipe. It was the intention that the engineering records should strongly recommend making periodic inspections of this pipe line and applying cathodic protection if and when required. A pipe line must have continuous electric bonding either through welded joints or by very generous bonds across joints in order that the cathodic method of protection may be applicable. A well-known coupling contains a metallic spiral spring in the rubber gaskets designed to furnish such a bond by the compression of the spring against the metal of the pipe and coupling.

This cathodic protection appears of such interest and potential importance to water supply engineers and owners that a general description and appraisal of the process which has been kindly furnished by one of the contributors outside the Committee membership has been included in this report. (See heading "Increasing Use of Cathodic Protection").

Concrete Incasement of Old Steel Pipe.—More than 22,000 ft of 10-in. and 14-in. pipe in the Vista, Calif., irrigation district have been saved from destruction and given a new lease of useful life in very corrosive ground by incasement in concrete reinforced by hoops and longitudinal rods and placed inside a metal form by pneumatic pressure.

TANKS

Within the past decade the large elevated tank has come into its own. The earliest steel elevated tanks (the first of which was built at Laredo, Tex., in 1893) were practically all built with hemispherical bottoms. This practically limited the size to small capacities unless a relatively large variation in head could be permitted. A notable exception to the ordinary range of sizes was the tank built for the Louisville (Ky.) Water Company in 1905. This tank stored 1,200,000 gal at a total height of 220 ft, a diameter of 45 ft, and a water-level variation of 87.8 ft. Such a range of head would ordinarily be undesirable. With the hemispherical type of bottom design, if the variation in head is kept within a reasonable range for large capacities, the diameter would become so great that the relation of the vertical side-wall height to the height of the hemispherical bottom would be all out of proportion. For all practical purposes, therefore, the hemispherical bottom tank was limited to about 250,000-gal capacity.

This inherent difficulty with hemispherical-bottom tanks led to the design of the ellipsoidal type of bottom, the vertical depth of which is about half that of the hemisphere. With this type of design it was practicable to build tanks of larger capacity with relatively lower head variation. This design is well adapted for capacities up to about 600,000 gal.

Beginning about 1930, elevated tank builders developed a design having a substantially flat bottom supported upon beams, girders, and columns which made it practicable to store water in any quantity desired, with substantially any range in head desired. Further variations in design have included oblate spheroids with bottoms flatter than tops and with water filling against the curving top as well as sides and bottom. These progressive improvements in design have been reflected in the growing use of large elevated storage tanks. The past fifteen years have seen the installation of more than 250 elevated tanks larger than 500,000-gal capacity, of which 77 were 1,000,000 gal or over.

Some of the contributing factors, other than the developments in design, which have brought about this great increase in use of large elevated storage capacities, are discussed separately herein.

Appearance.—Coincident with the developments in design, there has been a studied effort to make the elevated tank an attractive structure. This phase of the problem received a real impetus by a nation-wide competition of elevated tank designs conducted by one of the leading tank manufacturers a few years ago. Several hundred designs were submitted and substantial prizes were awarded for the best designs. Out of this competition grew an appreciation of the fact that an elevated tank need not be a blot on the landscape. Tanks now have a more streamlined appearance, the old conical roof has largely been supplanted by the graceful curved lines of the upper part of the tank, in which the roof serves as a water holder, and in many of the larger tanks tubular columns rather than structural built-up members have been used.

A notable illustration of this type of construction is the Blue Ridge tank recently completed at Indianapolis, Ind. In this tank the central riser is replaced by four centrally grouped tubular columns, thus better distributing the weight and permitting the center control compartment, or vault, to be placed in the center of the four-column group. One of these four central columns is utilized as the riser pipe connecting the tank to the distribution system. Another serves as an access tube to the tank interior, and within it is placed the ladder, overflow pipe, pressure pipe for flushing, and conduits for electric wiring. In addition to the four centrally grouped tubular columns, the tank is supported by twelve outer columns. All columns are 54 in. in diameter. The bottom of the tank is supported on twelve radial girders constructed as cantilevers, the outer wall of the tank being 9 ft outside of the row of columns.

Construction Methods.—Within the past decade elevated tank construction has changed from almost 100% riveted, to almost 100% welded, construction, particularly for the larger sizes. This change took place almost over night. Specifications for welded elevated tank construction are now in progress of preparation through a joint committee of the American Water Works Association and the American Welding Society. It is believed that they will be presented to the respective societies for approval during 1940.

Economics of Elevated Tanks.—The use of elevated tanks is no longer confined to small water works systems, as illustrated by installation of four tanks at Detroit (Mich.) of 1,500,000 gal capacity each, and one of 2,000,000 gal; Buffalo, N. Y., with three tanks of 2,000,000 gal each; Columbus, Ohio, with two of 1,000,000 gal, one of 1,500,000 gal, and one of 2,000,000 gal; Milwaukee, Wis., two of 1,000,000 gal each, Sacramento, Calif., two of 3,000,000 gal each, etc.

Unusual Designs.—Like all other engineering matters, the selection of type and dimensions of tank is largely dependent upon the local requirements. Illustrative of this fact are the installations at Kenosha and Racine, Wis. In each of these cities elevated storage was desirable in the amount of about 1,500,000 gal. It was found that, with the topographical conditions, distribution system layout, and the clear-water storage capacities at the filtration plants, it would be practicable to build a 3,000,000-gal stand-pipe for substantially the same cost as a 1,500,000-gal elevated tank. The top half would be available and used as high service storage and the bottom half would be made available by pumps, if desired, when the water level was drawn below mid-height. The lower level, in effect, is reserve clear-water storage capacity.

Sacramento is illustrative of a unique design in which a steel shell designed to resist full internal pressure is bonded with and encased in a concrete shell. The shell was poured while the steel tank was full of water so that the concrete is under no stress when the tank is full and in compression at all stages of lower water level. The design provides resistance to possible surge of the contained water that might be caused by an earthquake.

In the municipal water system of Syracuse, N. Y., a group of three large steel stand-pipes having a combined capacity of about 8,000,000 gal have been covered inside and out with reinforced gunite about 2 in. thick. The bottoms are entirely of reinforced gunite. Two existing tanks were coated with gunite several years ago and the gunite has remained thus far (1940) in good condition.

Protection of Tanks.—Paint continues to be used except in a few cases where tanks have been protected by the use of gunite, and recently by cathodic methods which will be mentioned subsequently herein. Standard red lead, with sometimes an admixture of litharge, continues to be used by many conservative engineers, but there has been a great increase in the use of synthetic vehicles wholly or partly replacing linseed oil and in the use of aluminum paint or mixtures of aluminum and other pigments, notably graphite. Although water works superintendents and engineers are ever optimistic, and listen with patience to descriptions of new paint products which are thought by their manufacturers to be superior to the old paints, there appears to be no conclusive evidence that modern paint has a longer life than the paint used in past decades.

In recent months the cathodic method of protecting ferrous metals, previously exploited and used to some extent for the protection of boilers, condensers, and heaters, and the kindred adaption of the cathodic process to the exteriors of buried pipe, have been adapted to the protection of steel tanks. Anodes of stainless steel or graphite are hung in the tanks and a direct electric current is passed in such a way as to make the tank cathodic, which tends to transfer the corrosive effects from the tank to the renewable anode rods. There are many of these installations recently made, beginning about 1936, but the Committee has been unable to secure a genuine appraisal of the effect as yet, although favorable opinions are expressed guardedly.

In one case noted, the throwing off of rust following the application of the cathodic method caused an old, very rusty tank to leak at certain seams and rivets. With new tanks, or tanks in good condition, there is promise, based upon the brief experience with tanks and on the longer experience with boilers, condensers, and the exteriors of buried pipe, that the method will be helpful in preventing corrosion.

Increasing Use of Cathodic Protection.—Cathodic protection as a means of protecting the exterior of pipe lines has been known for a number of years. In March, 1908, Herman Geppert obtained a German patent and in this patent mentions placing the anodes close to the pipe and connected to the positive pole of a generator while the pipes were connected to the negative pole of the generator. In 1910 Herbert W. Harker and Charles C. McNamara, Juniors, Am. Soc. C. E., gave the results of the use of cathodic protection in the prevention of corrosion of boilers. In 1915 a 60-in. steel gas main in New York was protected by cathodic protection by connecting the negative side of the generator to the pipe line and the positive side to an electrode placed in the East River.

These facts are mentioned, not as the total amount of work done in these years on cathodic protection, but to show that cathodic protection was recognized as early as probably 1905 and 1906. However, it was not until within the past ten or twelve years that the use of cathodic protection on pipe lines received very much attention.

During 1935 engineers throughout the United States were reporting results of cathodic protection installations to protect pipe lines. In those days the success of the installations was generally measured by the reduction in the number of leaks which occurred on lines that had been protected. For example, on one 5-mile section of a pipe line in Louisiana in the beginning of 1931 five leaks were reported. At the end of 1931, forty-two leaks were reported, and at the middle of 1932 fifty-five leaks were reported. At that time cathodic protection was installed and development of leaks continued for about six months following the installation, after which time the cathodic protection definitely prevented further development of leaks.

S. G. Rhodes was probably one of the first engineers to protect a large uncounted pipe line cathodically. One of his most recent installations is on a bare 24-in. steel water line[9] which is successfully protecting the line.

The extremely cold weather of 1936–1937 damaged numerous fruit trees in California due to freezing temperatures. As a result of this the California citrus growers installed a piping system near the surface of the ground conveying fuel oil to pressure burners distributed throughout the groves, which are burned when temperatures are low enough to harm the fruit trees. These pipe lines, being near the surface of the ground, were subject to rather severe corrosion and cathodic protection has been used successfully to protect these networks.

During the 1939 Golden Gate Exposition on Treasure Island in California, the networks of five utility systems were subject to the severe corrosion of the non-homogeneous, highly corrosive filled soil. Failures were so rapid that action had to be taken immediately to reduce the number of leaks. By the use of a combination of insulating joints properly installed and cathodic protection, pipe and cable failures have been practically eliminated. The status of this work is reported by W. E. Schneider.[10]

In the past few years practically all the oil and gas lines in the Southwest and Middle West are being protected in the "hot spots," or regions of corrosive soil, by cathodic protection. Many different types of installations are made. The most common source of power for cathodic protection of pipe lines is the copper oxide rectifier of a type developed for the purpose. This source of power seems to be the most satisfactory where power is available. Where power has not been available, such as on the oil and natural gas lines running through open country on right of ways, other sources of power have been used, such as gasoline-driven motor generator sets, natural gas-driven motor generator sets, storage batteries, and—one of the most recent developments—windmill generators. These windmill generators are mounted on a tower and have a large blade, which is driven by wind having a velocity of 4 miles per hr or higher.

Another method of generating current for cathodic protection has been the use of zinc bars placed in the ground adjacent to the pipe line. Probably the first use of zinc for cathodic protection was in boilers, where a nugget of zinc was placed inside the boiler and connected to the boiler sides. The bottoms of ships were also protected by this method years ago. Because of the potential difference generated by the dissimilarity between the metals, zinc and iron, current is driven through the soil from the zinc bars to the pipe line. It is reported that a 1-in. square zinc bar of pure electrolytic zinc would generate approximately 0.025 ampere when connected with the pipe line. These bars are placed adjacent to the pipe and spaced approximately 4 ft apart for 22-in. pipe, and approximately 10 ft apart for 8-in. pipe.

---

[9] "Cathodic Protection of a Bare 24-in. Steel Line," by T. C. Marshall, *Gas Age*, April 13, 1939.

[10] "Cathodic Protection on Treasure Island," by W. E. Schneider, *Gas*, August, 1939.

A cost analysis of one of the large installations of zinc anode cathodic protection shows that the actual cost for protecting 6-in. welded steel lines amounts to approximately 23.6 cents per ft of bare line, and for an 8-in. welded steel line approximately 25.2 cents per ft of bare line.

The cost of cathodic protection is controlled in the most part by the anode system used. Theoretically, the farther away from the pipe line that the anode can be placed, the larger the area of pipe that can be protected for approximately the same power cost. However, it is not always practical to place the anode at a sufficient distance from the line and in these cases the distributed anode system has been used. If any other structures are in the vicinity of the pipe line to be protected, such a structure might "shield" the pipe line from the anodic current with the result that corrosion of the structure might be quite serious. Therefore, it is impossible to apply cathodic protection to any one structure in a city network without giving due consideration to all the other structures present. Cathodic protection of mains joined with material that is not a good conductor should not be considered unless all such joints are bonded with a copper wire of sufficient capacity.

The use of cathodic protection for the protection of structures has increased by leaps and bounds within the past few years. Theoretically, it can be used as protection for practically any structure in any location, but there are some situations where the cost of installing cathodic protection might be prohibitive, such as in a city network where one structure is to be protected without the inclusion of other structures and where the anode would have to be placed immediately adjacent to the structure and extended over the full length to be protected. Another difficult and costly installation would be to attempt to protect the inside of a small water pipe line or to prevent corrosion produced by brass valves in small water lines. However, it can be used to protect pipe lines, water tanks, metallic building structures footed in corrosive soils, underground cable systems, inside of boilers, condensers, etc.

Practically all the companies owning underground piping or cable systems are successfully using cathodic protection in one form or another. Hundreds of miles of water, gas, and oil lines are now protected by this method. One company alone reports that the expenditure to date on cathodic protection amounts to several hundred thousand dollars.

WATER METERS AND GAGES

The types of water meter used to measure water delivered to domestic and other consumers are generally as follows: (a) Positive displacement meter, (b) current meter, (c) compound meter, and (d) fire-line, compound, proportional meter. There have been no material changes in the fundamental design of these meters, but improvements have been made in the choice of non-corrosive metals for the moving parts and casing, and in some cases the enclosure of the gear trains in oil.

Public-service commissions are prescribing narrower limits of accuracy than formerly, and flow tests resulting from this movement seem to prove that there is a much greater quantity of water consumed at low rates than was heretofore suspected. The net result has been more care in manufacture and the choice of material, resulting in greater accuracy.

The meters generally used for measuring the output of pumping stations and reservoirs are, in essence, rate-of-flow meters to which, in general, integrating devices are added to totalize the quantity of water passing. Improvements in meters of this category have continued during the past decade as indicated below. The propeller type has been improved by the use of chrome steel alloys for the bearings and the use of mineral base plastics for propellers, and these have been found not to crack or change in hot or cold water. Special meters of this type have been developed for use in open channels. One is installed in the new Croton Aqueduct at Dunwoodie Station, New York. Others will be installed in the intake channels of the filtration plant by the Metropolitan Water District of Southern California. Vertical installations have been used in the intake cribs in Chicago, Ill. A special meter for measuring the output of individual suction wells from 4 in. to 8 in. in diameter has been developed.

In place of a Venturi tube or an orifice, there have been a number of installations in which the losses in head in the tapered cones leading to pumps or the pump casings themselves or elbows have been used in connection with the indicating and recording devices. An open-flow nozzle for use with indicating and recording devices has been developed and used. Further fundamental research work for establishing the law of Venturi-tube coefficients with changes of size and ratio of throat to main has been done to a considerable extent during the decade.

In 1936 the Joint Committee of the A.G.A. and American Society of Mechanical Engineers (A.S.M.E.) published the results of its work on the determination of coefficients for the thin-plate orifice. Reynold's numbers have been used in the mathematical classification of the results. This work is being used by instrument companies.

Devices have been invented and used by which the head at the throat or orifice may be negative without injury to the accuracy. The primary and the secondary elements of these meters are connected by tubes containing air instead of water. Summation indicators and recorders are also in use which totalize the flow of several Venturi meters as well as indicate the difference between the flows of two or more Venturis. Meter tubes and indicators which will measure flow and indicate and record flow in either direction are in use. Indication and control of the ratio of rates of flow through two Venturi meters can be had; so also can be had meters to act as controls for chemical feed equipment, automatic water softening equipment, etc. A new principle for totalizing the flow has been developed which utilizes the force developed from a gyroscopic couple.

Telemeters and Telegages.—There have been many developments during the decade in the art of indicating totalizing and recording rates of flow and indicating and recording pressures at a distance. Some of these make use of rented telephone wires and others are operated through special wires. One of these systems, which may be defined as the time-impulse system, is a distinct product of the past decade and is in extended use in important water supplies.

Parallel with the development of telemetering and telegaging has come the distant control of valves and pumps. The operator in this case is able to see exactly what he is doing by the indications of telemetering and telegaging devices. There are important installations of this kind both in Baltimore and in Pittsburgh.

TEN YEARS' PROGRESS IN CENTRIFUGAL PUMPS

During the past 10 years the changes in centrifugal pump design have not been of a radical nature but have had mostly to do with refinements to produce higher efficiency and longer life.

Standard Pumps.—In the standard type of pump, of moderate size, there has been a distinct shift from sleeve to ball bearing, although there are many large operators who still prefer the sleeve type. The use of ball bearings, particularly on relatively small pumps, permits of closer running clearances, thereby reducing the leakage through the rings, and resulting in improved efficiency. In the larger pumps, however, it is still common practice to use sleeve bearings with the outboard equipped with a ball thrust bearing as well to take any unbalanced thrust that might occur due to changes in hydraulic conditions. Efficiencies are becoming higher year by year, 88 or 89% not being at all unusual for a pump operating under favorable conditions.

Large Centrifugal Pumps of High Efficiency.—The peculiar needs for boosting a large quantity of water over the high divide traversed by the new aqueduct which will carry water from the Colorado to the Metropolitan Water District of the Los Angeles region caused the development of vertical centrifugal pumps of very high efficiency—that is, approximately 92 or 93%. A difference in operating efficiency of 1% on all the pumps in various booster stations along this aqueduct meant a gain or loss of about $40,000 per yr in power costs. These pumps have lifts of 440, 300, and 150 ft, respectively, and capacities of about 130 mgd each. Pumps of about this efficiency have been obtained in other large installations.

Mixed Flow and Propeller Pumps.—In the large capacity and low-head field, the mixed-flow and propeller-type pumps have been progressing rapidly—the mixed flow particularly in sewage work and the propeller type in the drainage field. Inasmuch as the characteristics of these pumps, particularly as to horsepower, vary from the straight centrifugal unit, it is quite important to give these features close study, especially where synchronous motors or rigid starting current limits are involved. Pumps of these two types have the great advantages of being somewhat cheaper and are suitable for operation at higher speeds without sacrifice of efficiency, thus causing some saving in space and additional saving in the price of the driving motor. Most of these pumps are of the vertical type.

High-Pressure Pumps.—High-pressure, multi-stage pumps continue to be used and have been developed for very high-pressure boiler feed and hot oil pumps. Most of these installations have proved to be very satisfactory.

Well Pumps.—Three developments in well pumps are noteworthy. First is the increasing trend toward the use of water lubrication. The development of the rubber cutless bearing combined with the use of extremely hard metal for shaft journals has greatly increased the use of this type of lubrication.

Second is the development of the so-called submersible pump in which the motor is placed below the pump to which it is directly connected and the entire unit is submerged in the water of the well. The unit is thus close-coupled without a long shaft and has the advantage that it is noiseless, can be placed in a crooked well without bending the shaft, and requires no chamber to cover the motor. A considerable number of these units are in use. The type most commonly used employs a mercury seal to keep the water from the motor, which runs in oil.

The third development is that of a small, efficient, helical pump to operate at speeds not greater than 1,750 rpm with capacities of 10 to 75 gal per min in wells of 4-in. and 5-in. diameter. This has been a field dominated in the past almost entirely by the piston type of pump.

Methods of Drive.—In pumping stations, the electric motor drive is "holding its own" rather well, but increasing thought is being given to the use of Diesel engines with step-up gears driving the pump at, say, 1,800 rpm, thereby obtaining a light and efficient unit. The pump and gear are less expensive than the larger pump of low speed which would be suitable to be direct-connected to the engine. The Diesel drive, of course, is very well adapted to pumping into a direct system as it permits easy speed variation to meet demands without appreciable loss in over-all efficiency or the necessity of costly speed control, as frequently occurs in the case of the motor units. In many cases a generator also can be driven by the same engine, thereby producing power for well and small booster pumps, station auxiliaries, etc. In stations where the total horsepower is from 100 to 400, and where little or no reservoir capacity exists, it is quite likely that this type of unit will come into more general use.

Motor Mounted Pumps.—In the past few years the small, separate pump and motor have been largely replaced by the block-type unit, where the pump case is mounted on an extension of the motor frame, doing away with coupling or pump bearings. These units save space and are cheaper than the four bearing unit.

WATER HAMMER

Water hammer has received an increasing amount of attention during the past decade. In the case of penstocks for hydroelectric power, mathematical predictions as to the intensity of water hammer and provisions for limiting the intensity have been the rule for many years; in recent years supply mains and force mains are receiving similar attention from well-informed engineers.

Whenever the rate of flow in a pipe changes there is a pressure rise or fall which may be large if the alteration in discharge is great. The connection between the change in discharge and pressure rise is somewhat complicated, but may be explained briefly as follows:

When, for instance, water is flowing through a valve at the end of a long pipe connected to a reservoir and the valve is quickly partly closed, a decrease in the pipe velocity results and this is accompanied by an increase in pressure. This pressure rise starts at the valve and travels up the pipe at nearly constant pressure, until it reaches the open reservoir, and from there is reflected back as an equal decrease in pressure which finally reaches the valve; from the latter it begins its cycle over again. These pressure "waves" move at from 2,500 to 4,000 ft per sec, and are finally extinguished by friction. Should the valve be closed before the return wave reaches it (that is, within 2 sec in a pipe 2,500 ft long for the lower wave velocity), there is a pressure rise amounting, in feet, to approximately one hundred times the original velocity of the water; but the rise in pressure is very much less if the time of closure is at least twice the time taken for the wave to make its return trip. The rise in pressure is independent of the pipe length so long as the closure is quick enough.

For the ordinary gate valve on a long pipe, perhaps 70% of the gate closure may be made before the discharge is much affected, and this part of the movement may be made very quickly, but the last 30% of the movement, which is really the effective part, should be made with caution. The matter has been discussed in a paper entitled "The Action of Valves in Pipes," by R. W. Angus.[11]

For short pipes, gate-valve closure rarely can be made before the pressure wave returns to it because of the short time elapsed, and therefore short, ordinary pipes with gate or globe valves are in little danger from water hammer. A serious source of trouble, however, and one only recently fully appreciated, may arise in pipe lines supplied by electrically driven centrifugal pumps when the power supply fails suddenly. Most of these pumping units have very little inertia and consequently begin to slow down almost instantaneously after the driving power ceases; and being unable to maintain the head on the system, they cease pumping. Only the momentum of the water in the pipe maintains the flow, which continues upward through the pump, the pressure at the latter being practically atmospheric. As soon as the energy in the water is spent, the column begins to reverse, flowing downward through the pump, which frequently runs backward, and the water acquires a very high velocity unless hindered in some way; it then often happens that the check valve, always used on such systems, suddenly closes and there is a corresponding pressure rise and shock, which are often surprizingly great. The ordinary check valve is capable of closing very rapidly once the flap starts to move downward, and short, low-pressure pipes are usually in more danger than larger ones because the momentum of the water is small and reversal of flow may occur before the check valve has time to move. One case was observed on a sewage pump with ordinary check valve working against a static head of 56 ft and delivering 3,930 U. S. gals per min through 338 ft of 20-in. pipe, in which the pressure rise, due to sudden shutdown, was about 60 lb per sq in., and the blow actually shook the pump every time the power failed. In this case the reversal of flow was quick, but in a pipe several miles long, reversal may require more than 25 sec, giving the check valve ample time to close safely.

Various types of check valves have been devised to avoid danger, these being usually of a type in which the first part of the closure is rapid and the final part is slow; for a long pipe it is stated that an ordinary check valve, with a dashpot to prevent rapid final closure, is effective, particularly if a small, open by-pass is made around the valve to prevent the sudden extinction of the final part of the flow. Such a valve has been developed in Canada.

---

[11] *Journal*, A. W. W. A., Vol. 30, November, 1938, p. 1858.

Another cause of trouble from power failure is due to the sudden change in slope in hydraulic gradient, because after pumping stops the gradient will slope downward from the reservoir surface to the pump and may easily cut the pipe axis. Should it fall 34 ft or more below this axis, there will be a separation of the water column, the two parts traveling at different velocities; and when reversal of flow occurs the columns will re-unite and a dangerous pressure may result. Admission of air at the high point, and its later release, and the use of a proper type of check valve, should prevent trouble.

Distribution networks of cities and towns are not usually dangerously affected by water hammer, except through some accidental cause, such as sudden closure of a locomotive filling valve or fire stream, or the shutting down of a pump. In these systems the wave, which starts at the trouble making valve, travels into all distribution branches where it changes its rate of travel and its pressure rise according to the size of pipe in which it moves. Dead ends may be a source of danger, but usually in networks there are enough open branches to damp out the pressure wave before damage is done; theoretical study of these systems offers only as much difficulty as is experienced in the design of them for proper distribution, and quite good approximation may be arrived at.

It is now recognized that care should be taken in the type of service sold from a system. Many locomotives draw directly from a fairly long isolated pipe with a quick-closing valve at its outlet, and there is every possibility of the full flow being stopped before the return wave has reached the valve; such lines should have valves that cannot be closed rapidly, and, if necessary, should be equipped with dashpots. The fact that the pressure wave travels through the system shows that a pipe may break a mile away from the locomotive, if the valve is closed quickly enough.

The profession is in need of help from operating engineers who can furnish much data from which the present theories can be corrected or checked. The following types of information would be most helpful: (*a*) In cases of pipe bursts due to suspected water hammer, what are the sizes and lengths of pipes and what was the water velocity? (*b*) Was there a power interruption at the pump house? (*c*) What type of check valve was used? (*d*) Did the pump reverse, and what was the maximum pressure recorded at the station? (*e*) Are any data available as to the parting of the water column at pump cutout in a pipe line which has a sudden change of gradient? (*f*) What has been the experience with cone or other types of special check valves in reducing water hammer? (*g*) Has any trouble been experienced with low-head installations, such as those in which water is being lifted to filter beds; if so, what has been its nature? (*h*) What information is available about broken check valves?

Reliable pressure records of water hammer may be obtained by means of a steam-engine indicator recording on a drum, 4 in. to 6 in. in diameter, driven by a synchronous clock motor. Recording gages are usually too slow in action, but may sometimes be adapted to the work if only slightly altered.

When engineers cooperate by sending, to some central body, details of their water hammer experiences, the present theories will be very much improved and simplified.

PROGRESS IN WATER TREATMENT AND FILTRATION IN THE DECADE 1930–1939

Great progress in the treatment and filtration of water has been made within the past decade. New treatments have been introduced, and, although there has been no material change in the design of water purification plants, there has been improvement in the operation and maintenance of the plants. The use of activated carbon for taste and odor removal, ammonia in connection with chlorin for better sterilization, acid-treated sodium silicate for improving coagulation, and sodium hexametaphosphate for preventing precipitation of calcium carbonate and for corrosion control are the main developments in the treatment of water. Effort to maintain filter beds in good condition and improved laboratory technique have been the main development in plant operation. The addition of surface washes to filters and the flocculator type of mixing basin have been the main improvements in design.

TREATMENT OF WATER

Activated Carbon for Taste and Odor Removal.—The most important development in the treatment of water has been the use of activated carbon for removing objectionable tastes and odors. Experiments in 1928 and 1929 indicated that activated carbon was a practical means of removing tastes and odors from water, but it was not until 1930 that this material began to be used in the treatment of public water supplies. The use of carbon in the powdered form has extended rapidly since that date, and by the end of 1939 it was being used at least part of the time in nearly one thousand water filtration plants. The material was first used sparingly, and, although it produced some improvement in the quality of the water, the taste and odor were not eliminated completely.

Within the past several years increasing quantities of carbon have been used, and efforts to reduce the taste and odor compounds below objectionable concentrations are rapidly becoming the practice in all well-operated purification plants. There are instances where, for periods of short duration, the amount of carbon required to give satisfactory elimination of taste and odor has exceeded 1,000 lb per million gal. This represents a cost between $30 and $40 per million gal for taste and odor elimination alone. The use of any material in amounts that require such a high expenditure shows the importance placed upon the palatableness of water.

There are several places where beds of granular, activated carbon have been installed for passing the filtered water through the beds, but decidedly the greatest use of activated carbon is in the powdered form. The powder is added to the water in advance of filtration, and is removed by the filters. Not only was the use of activated carbon in water treatment developed in the decade just ended, but there has been great improvement by the manufacturer in the absorptiveness of the carbon. The better grades of carbon are now more than twice as absorptive as they were when carbon first was used. In addition, the price of the material has been reduced. The cost of removing taste and odor from water by the use of activated carbon is now less than one third the cost when carbon first began to be used.

Ammonia.—Another outstanding development in the treatment of water within the past 10 years is the use of ammonia for lessening chlorinous taste and for producing better sterilization of water. Like activated carbon, the effectiveness of ammonia in lessening chlorinous taste was established 2 or 3 years prior to 1930, although its extensive use did not start until then. Now (1940) a large number of water purification plants use ammonia.

Ammonia lessens the rate at which residual chlorin disappears in the water, and it is possible to maintain residual chlorin throughout practically the entire distribution system. Furthermore, it is possible to maintain a higher residual chlorin in the water than heretofore without producing objectionable chlorinous taste.

Fluorin Affects Teeth.—That certain waters cause defective tooth enamel seemed well established in 1926, although the substance causing the effect was not then known. In 1931 fluorin was found to be present in considerable quantities in several waters where mottled tooth enamel was of frequent occurrence and was suspected of being the cause. Definite proof that fluorin was responsible soon was established. Means of removing fluorin from water have been developed although the cost is still too high to be extended to public supplies if other sources of water are available at a reasonable cost.

Silicate Treatment.—The presence of silica in water was found to have considerable influence upon coagulation of the water with aluminum sulfate. This discovery led to the development of a silicate prepared by acid treatment of sodium silicate which will aid the coagulation of water with aluminum sulfate and ferrous sulfate. Use of the silicate to aid coagulation is likely to be extended to a number of water supplies where the water does not coagulate easily.

Softening.—Continued progress has been made in water softening, although there have been no major developments in the treatment. A number of plants using the lime-soda process have been constructed. The use of zeolite for softening municipal supplies has been extended also. The addition of carbon dioxide to lime-soda treated water for preventing incrustation of the sand grains in the filter beds and deposit in the piping distribution system is becoming common practice. Recently, sodium hexametaphosphate has been used to prevent lime incrustation, and there are indications that this material may be used to considerable extent in water softening plants using the lime-soda process. Also it has the possibility of aiding in pipe-corrosion control.

Flow through thickly concentrated and agitated sludge to hasten the softening action, followed by upward flow through a sludge blanket, has been developed as a substitute for the usual type of lime-soda softening plant. These devices are known as "accelators" or "precipitators."

BETTER OPERATION

There has been considerable improvement in the operation of water purification plants within the past decade. Chief interest has been directed to maintaining the filter beds in better condition, to good conditioning of the water before filtration, and also to improved sterilization of the water.

Turbidity of Filtered Water.—Accurate measurement of the turbidity of the filtered water has become common practice. This is resulting in clearer water being produced by the plants. Instruments have been developed for making low turbidity measurements and, although some of these instruments were developed prior to 1930, very few filtration plants made accurate measurements of the turbidity of the filtered water prior to this date. In many plants the turbidity of the filtered water is maintained below 0.2.

Odor-Threshold Test.—Use of the odor-threshold test as a guide to taste and odor removal treatment has become common practice. The water is diluted with odor-free water to the extent that the odor is just detectable. Operators now attempt to reduce the odor to some definite odor threshold.

Bacterial Quality of Water.—There has been improvement in the bacterial quality of the water in many filtration plants within the past few years. Several outbreaks of gastro-enteritis have caused present requirements for the bacterial quality of water to be questioned by a few. As a result, higher chlorination is being used in many plants. Prechlorination, used to a limited extent prior to 1930, is now (1940) the practice in a number of filtration plants. The superchlorination of water has made little progress, although it received renewed attention in 1939. High chlorination is used for two purposes—one to produce better sterilization of the water, and the other to aid in reducing taste and odor. The present indications are that there will be extension of high prechlorination treatments for these two purposes.

Sterilization of New Water Mains.—In some cities it has been the practice for years to sterilize new water mains before placing them in service. Within the past decade it became common practice in nearly all cities. The difficulty in obtaining good bacterial samples from new mains, even after sterilization, has been so great in some places that consideration is being given to the use of material other than jute for packing the joints. Sterilizing of jute by steam seems to be successful in permitting sterilization of mains.

DEVELOPMENTS IN FILTRATION PLANTS

Mixing Basins.—The mechanical type of mixing basin is being installed in nearly all of the new filtration plants. There has been a drift toward the use of mechanical mixers of the flocculator type. In some plants there are two stages of mixing. The first stage is rapid initial mixing, and the second stage is gentle agitation for forming the coagulation into large flocculated particles.

Settling Basins.—There has been little change in the general design of settling basins within the past decade. Most of the softening plants have settling basins equipped with continuous sludge-removing equipment. Two-story settling basins have been constructed in two or three filtration plants, and such basins are included in the design of the new filtration plant for Chicago. Local conditions, which made deep basins desirable, was the reason. There was no belief that a two-story basin is superior to the usual type of settling basin.

Filters.—The design of filters has remained largely the same within the past decade, but there has been considerable improvement in some of the parts of the filter. Surface washing systems have been installed in the filters of a number of filtration plants. The high rate of wash—that is, a rate to expand the bed about 50%—is being used in many places. There has been a drift toward the use of coarser filtering materials and higher rates of filtration. The use of crushed anthracite coal in the place of sand for the filter beds has been adopted in a few plants. The design of the filter underdrainage systems has not undergone any material change, although porous-plate filter bottoms are being tried in a few filtration plants. These plates are intended to eliminate the necessity for using gravel in the filters. Filter-rate controllers have been simplified and made more positive in their action.

New Filtration Plants

The construction of new filtration plants was almost at a standstill during the first 3 or 4 years of the depression (1930 to 1933, inclusive). However, since then a large number of plants have been constructed, and others are under construction. Many of the older plants have been extended and the treatment facilities improved.

Trends in Valuation of Public Utilities

The decisions of the United States Supreme Court are the milestones which indicate directional trends in valuation practice. Such decisions arise from cases brought before the court by the utilities on claims of confiscation under the due process clauses of constitutional amendments IV and XIV.

These decisions, although frequently expressing definite opinions on important phases of valuation philosophy, are more frequently only indicative of the court's position by refusal to disapprove the action of some lower court or regulatory commission.

Interpretation—involving the personal equation and perhaps requiring more legal knowledge than is vouchsafed to the run-of-the-mine engineer—is necessary, therefore, and any attempt by an engineer to deduce directional trends is more or less foolhardy. The following is offered with the realization of the limitations of engineers acting alone without benefit of counsel.

The United States Supreme Court first announced its general theory of valuation for rate-making purposes in the Smyth-Ames case (169 U. S. 466)—namely, that a utility is entitled to a reasonable return on the fair value of its property devoted to public service, and that, in determining such fair value, actual cost, reproduction cost, earning capacity, and various other factors are "all matters for consideration and each to be given such weight as may be just and right in each case."

The court has held to this general principle for more than 40 years, but without determination of the weight to be given to the various factors and not without repeated differences of opinion in the court as to their relative import. As an example of these differences, Justice Felix Frankfurter, in his minority opinion in Driscoll versus Edison Light and Power Company (28 P. U. R. (N. S.) 66 April, 1939), wrote: "The decree below was clearly wrong. But in reversing it, the court's opinion appears to give new vitality needlessly to the mischievous formula in fixing utility rates in Smyth-Ames."

As to the determination of cost, the U. S. Supreme Court has not established the relative weights to be given to actual and to reproduction cost. Leading cases following the World War of 1914–1918 gave increased importance to reproduction cost, and in McCardle versus Indianapolis Water Company (272

U. S. 400, 1926) predominant consideration was given this factor. Since 1930, the tendency appears to be more toward actual cost. Thus, in Los Angeles Gas and Electric versus California Railroad Commission (289 U. S. 287, decided May, 1933), actual cost is emphasized, and a similar broadening of historic cost in rate-base determination is indicated in Clark's Ferry Bridge Company versus Public Service Commission of Pennsylvania (2 P. U. R. (N. S.) 225, decided February, 1934), and in Dayton Power and Light Company versus Ohio Public Utilities Commission (3 P. U. R. (N. S.) 279, decided April, 1934). In his minority opinion on Driscoll versus Edison Light and Power Company (supra), Justice Frankfurter commends the practice of the Massachusetts Commission of using prudent investment as a yardstick of value. Likewise in McCardle versus Indianapolis Water Company (38 P. U. R. (N. S.) 468), Justice Hugo L. Black, in dissenting, refers to "imaginary reproduction value." These references are from minority opinions but may be significant in view of the rapidly changing personnel of the U. S. Supreme Court.

The recent practice of public service commissions has indicated a tendency to establish, as of some date, a rate base—whether founded on actual or reproduction cost—and to go forward therefrom on the basis of actual cost.

In reference to going value, recent decisions of the U. S. Supreme Court indicate a definite tendency on the part of the court to require that going value, if allowed, be adequately proved with respect to the particular property being valued. As stated in the Dayton Power and Light Company versus Ohio Public Utilities Commission case, decided by the U. S. Supreme Court April 30, 1934, "Going value is not something to be read into every balance sheet as a perfunctory addition." As stated in the Los Angeles Gas Corporation versus Railroad Commission of California, "It calls for consideration of the history and circumstances of the particular enterprise."

The reasonable rate of return has been related, in general, to the prevailing interest rates. Previous to the World War of 1914–1918, 6.00% was generally allowed. Under postwar conditions between 7.5 and 8.0% was considered necessary to avoid confiscation. In the Indianapolis Water Company case (1926) it was held that "the evidence is more than sufficient to sustain a rate of 7.0% * * * and recent decisions support a higher return." In Driscoll versus Edison Light and Power Company (1939) (supra) a 6.0% return was held not to be confiscatory.

In brief, decisions of the U. S. Supreme Court during the past decade seem to point to an increasing recognition of actual cost in the determination of fair value, a minimizing of going value as a separate element (except in so far as it is proved in each case), a downward trend in the rate of return, and, in general, a tendency to grant a wider discretion to the state regulatory commissions.

ACKNOWLEDGMENTS

The Committee has sought and received the aid of a number of engineers and specialists not enrolled in its membership and wishes to acknowledge with gratitude its indebtedness to the following persons: Prof. Robert W. Angus, for the technical portions of the section on Water Hammer; Frederick W. Scheidenhelm, M. Am. Soc. C. E., for the section on Masonry Dams; W. P.

Creager, and J. D. Justin, Members, Am. Soc. C. E., for much of the matter used in the section on earth dams; Frederick H. Fowler, M. Am. Soc. C. E., for a very complete article on rock-fill dams which was necessarily condensed to accommodate the available space; Henry Horandt, for much of the data used in the section on meters; and A. V. Smith, for the section on the increasing use of cathodic protection. Various producers of pipe and pipe protection at the Committee's request supplied statistics as to use of improved linings. Pump manufacturers supplied information relative to progress in the manufacture of their products.

AMERICAN SOCIETY OF CIVIL ENGINEERS
Founded November 5, 1852
TRANSACTIONS

Paper No. 2097

THE RELATION OF THE SOCIETY TO NATIONAL DEFENSE

ADDRESS AT THE ANNUAL CONVENTION, DENVER, COLORADO, JULY 24, 1940

BY JOHN P. HOGAN,[1] PRESIDENT, AM. SOC. C. E.

It has been customary for the President of the Society to prepare an Annual Address early in the summer, and, after careful editing by the staff, to have it published well in advance of the Annual Convention and distributed in pamphlet form. The march of events has been so rapid in the past six months that it has seemed to me that such an address would totally disregard the realities that confront us at the moment and those that may confront us in the near future. I therefore propose to devote a considerable part of my address to the subject in which the engineers of the country are most vitally involved—the subject of National Defense.

Before proceeding to this vital topic I wish to report on the state of the Society. This can be done in part only by the President, since, like a butterfly, he flits in and out yearly, whereas the management is carried on year in and year out by the members, acting through the Local Sections, the Board of Direction, and our hard-working and efficient staff. During the ten years of depression, or partial depression, through which we have passed, the activities of the Society have been greatly increased and decentralized.

We have 64 Local Sections, to which all of the members have been assigned, and to whose support the Society contributes nearly $22,000 a year. The Board of Direction has delegated to these Local Sections an increasing amount of its authorities and responsibilities as rapidly as the Local Sections have been organized to assume them, reserving only the right of review and of formulation of general policies. As a measure of this decentralization I can state that when I first came on the Board of Direction in 1922 the meetings of the Board consumed three days, whereas at the Spring Meeting in 1940 one day was sufficient.

The Technical Divisions have grown in number, size, and importance. With *Civil Engineering* as a vehicle, these Divisions have afforded an opportunity for the discussion of many technical topics of current interest, and have provided more serious discussions and theories for technical proceedings. The latter, as published in *Proceedings* and *Transactions*, have maintained their former high standard of excellence.

---

[1] Parsons, Klapp, Brinckerhoff & Douglas, New York, N. Y.

The Society has reached one of its peaks in membership, totaling today (July, 1940) approximately 16,500 in all grades, of whom about 4,000 are Juniors. In addition there are 6,000 members of Student Chapters in 123 technical universities and colleges throughout the country who are affiliated with the Society. Since there were only about 500 Juniors in 1919, and no Student Chapters, the accession to interest or membership of more than 9,000 youths has brought additional problems.

The first has been a demand for earlier and more intensive teaching of ethics, professional relations, and behaviorism. We are working to satisfy this demand.

The second has been the desire of these younger members and affiliates to educate themselves so as to be able to present and discuss their problems publicly. This is being handled by the Local Sections through the organization of Junior and Student Chapter forums, the presentation of prizes for papers, and special provisions for the presence of both groups at meetings.

The third has been the increased demand for more welfare service; this demand has not been confined to the youth. It is the sense of your Board of Direction that this demand should and must be satisfied, insomuch as it does not interfere with the legal status of the Society.

The management of the Society is to be congratulated that we have come through the depression with our assets unimpaired, our budget balanced, and our activities and usefulness increased, but there are certain red lights ahead, of which the principal one is the uncertainty of the times and what they may bring forth. Furthermore, Past-President Sawyer pointed out to you last year that the Corporate Membership of the Society has been steadily declining, and that our membership has been maintained only by the greatly increased number of Juniors. Largely through his efforts, membership drives were quietly started in a number of localities. These should be continued and extended to other localities.

The Society takes great pride in the technical achievements of six great permanent branches of the government services: The Coast and Geodetic, the Geological Survey, the Bureau of Public Roads, the Bureau of Reclamation the Corps of Engineers, and the Tennessee Valley Authority. In general, it is my belief that the new or emergency engineering organizations have not been particularly competent or efficient. I am opposed to the creation of more such organizations and in favor of "winding up" those already existing as rapidly as possible.

In speaking of National Defense, a subject much in the public mind today, the commonest question of the isolationist, or pacifist, is: "Why should any one attack us?" Why did they attack Poland, Norway, Holland, Belgium, and France? In fact there are many reasons why they should and will unless we are able to defend ourselves. One answer alone is enough. For the past two years all the movable wealth of Europe in the form of gold, securities, diamonds, etc., has been moved into the United States. Ships slip into New York Harbor with 50 to 60 million dollars worth of gold on board, without comment, although two years ago it would have created a sensation. One shipment from a small non-belligerent country included 125 million dollars in gold and a billion and a quarter in securities.

As a people we are prone to sign a check and forget about it. In this liberal and careless spirit we have just appropriated about 10 billion dollars for national defense. What have we now, and what will the new money do for us?

We have an efficient navy but most of the capital ships are old and slow. Some replacements may be expected within the next two years, but the capital ships provided by the present appropriations will not come into a service for four years.

If our navy is unable to protect us, what have we on shore? We do not have enough modern armament, ammunition, or high explosives for our present small army and National Guard, and we will not begin to produce enough for about eight months. Proper arms and ammunition for the minimum defensive army of 2,000,000 men will probably not be available until the fall of 1942.

We still have last hopes in aviation and luck, but neither of these will protect us from an economic strangulation through the loss of our foreign trade; we have already lost the trade of Europe and China. Notwithstanding the fact that we are at least a year late, we should, nevertheless, go ahead vigorously to make up for our neglect; and the Society, together with the other Founder Societies, the architects, and contractors, has cooperated since last February with the Army and Navy Munitions Board to this end.

I would like to emphasize the fact that the Construction Advisory Committee to the Army and Navy Munitions Board, which has been working for the past four months and has actually been commissioned since May 6, is composed entirely of the heads of the various organizations in the industry or their designees, and is therefore truly representative of the construction industry. I am proud of the fact that five out of the six members of the Committee are also members of the Society.

I should also like to make it very clear that the Committee has confined itself solely to questions of policy and has not attempted any selection. It did, however, initiate the formation of the Committee on Preparedness of all national engineering societies, and the architects, for the purpose of census and classification of personnel under the chairmanship of George T. Seabury, M. Am. Soc. C. E., Secretary of the Society.

The general purpose and aims of the Advisory Committee to the Army and Navy Munitions Board have been:

(1) To secure proper legislation permitting the use of management contracts on fixed fees. This has been accomplished.

(2) To prevent, as far as possible, the letting of agency contracts to manufacturing concerns to design, construct, and operate, because of our firm belief that this procedure would only result in confusion and, probably, scandal.

(3) To have satisfactory forms of construction contracts approved for management construction. This has been accomplished.

(4) To segregate engineering and architectural contracts from construction contracts. This has been established in principle in the army and representations have been made to the navy to correct some present difficulties.

(5) To establish the principle that there shall be no competition in fees. This seems to be generally accepted but the situation needs watching.

(6) To establish suitable regulations and forms for sub-contracts of all forms. This has been accomplished in the army but still remains unsatisfactory in the navy where the engineer, or architect, may be in the position of a sub-contractor.

(7) To establish the principle of utilizing the services of existing engineering and architectural firms for design instead of expanding existing organizations. This has been established in principle in both services but will be more utilized by the army on account of its greater needs.

(8) To urge as widespread geographical distribution as possible of technical and construction contracts to avoid overloading and favoritism. In this connection attention is invited to the practice of the architects in the New York City Working Development of taking in local associates to assist and share in the work of the principal architects.

(9) To prevent undue migration of technical and construction personnel either between different government jobs or between these jobs and normal construction work already in progress or anticipated.

(10) To insure adequate compensation for engineers and architects under the various classifications.

(11) To insure adequate fees for consulting services.

Due to the appointment of the Advisory Board to the National Defense Council by President Roosevelt, and the doubt in regard to the relation between the two committees, it has been necessary for this Committee to work in confidence. However, in June of this year W. S. Knudsen appointed William Harrison, chief engineer of the American Telephone and Telegraph, as his construction adviser, and the latter selected S. F. Voorhees, M. Am. Soc. C. E., and past-president of the American Institute of Architects, as a member of our Committee and as his assistant. It is the present intention that our Committee will remain as advisory to the Army and Navy Munitions Board, recommending on technical matters through it to the Services, and on questions of policy, to the National Advisory Board.

The question of engineering personnel for our armed forces may later become of moment should there be an immediate increase in the army. During the last war engineering troops formed about 7% of the army. An immediate increase to 10% is contemplated in our existing forces. It is reported that in the German army engineering troops form about 14%.

I have dwelt on this subject at length because it is something we have neglected too long. This is a familiar spot for the engineer, however, for he is often called upon to do immediately something that should have been done a year before. I am sure the professions will respond to the limit of their abilities.

In closing I can only quote to you the words uttered by John Curran 150 years ago, and published in the Saturday Evening Post.[3]

> "It is the common fate of the indolent to see their rights become a prey to the active. The condition upon which God hath given liberty to man is eternal vigilance; which condition if he break, servitude is at once the consequence of his crime and the punishment of his guilt."

---

MEMOIRS OF DECEASED MEMBERS

CHARLES DAVID MARX, Past-President and Hon. M. Am. Soc. C. E.[1]

DIED DECEMBER 31, 1939

Charles David Marx, emeritus professor of civil engineering, after a lingering illness died in his home in Palo Alto, Calif., on December 31, 1939. On this last day of the decade passed a famed member of Stanford's "Old Guard," a teacher who throughout a long life served well his community, his state, and his nation.

"Daddy" Marx—as he was affectionately called even when as a young man he established the Civil Engineering Department at the opening of Stanford University, at Stanford University, Calif., in 1891—was born in Toledo, Ohio, on October 10, 1857, the son of Joseph Eugene and Johanna (Pulster) Marx.

His father, who was born in Germany, came to the United States soon after the troubled year 1848 and was a journalist most of his life, remembered as a founder of the Ohio *Staats-Zeitung* (later The Toledo *Daily Express*). By appointment of President Lincoln during the Civil War, Joseph Marx served as American consul in Amsterdam, the Netherlands, from 1863 to 1866.

In this Dutch city Charles D. Marx spent several boyhood years. To supplement his private education in Amsterdam, he attended public schools in Toledo for a few years after 1866. Returning to his father's former homeplace in Baden, Germany, the youth studied at the Karlsruhe Realgymnasium, from which he was graduated in 1876. One of his teammates on the rugby squad at this school was F. Marion Crawford, the writer.

In the fall of 1876 Mr. Marx entered Cornell University, at Ithaca, N. Y., and was awarded the degree of Bachelor of Civil Engineering, with the class of 1878. Abroad once more, as a graduate student at Karlsruhe Polytechnicum, at Karlsruhe, Germany, he was named an assistant instructor in 1880–1881, and passed the Diploma examination as civil engineer in the same year.

Back in the United States, the young engineer was employed first by the Boston, Hoosac Tunnel and Western Railroad Company, successively as levelman, transitman, and assistant engineer on their proposed western expansion. He then became an engineer for the federal government on both the Mississippi and the Missouri River improvement projects, until Cornell University called him to serve as assistant professor from 1884 to 1890.

During the summers of his Cornell years he acted as inspector and assistant engineer, and at one time was principal assistant to the late Emil Kuichling,[2] M. Am. Soc. C. E., then city engineer at Rochester, N. Y.

An incident that was to influence his life came when, traveling on a train to a Cornell meeting in Ithaca, he became acquainted with David Starr Jordan. The first president of Stanford was so impressed by the young man that, when the University was opened in 1891, "Daddy" Marx was offered the first chair in engineering.

---

[1] Memoir prepared by a Committee appointed by the Board of Direction of the Society, consisting of John D. Galloway, F. H. Fowler, S. B. Morris, Leon B. Reynolds, and C. B. Wing, Members, Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXIX (1915), p. 1438.

Professor Marx was serving at that time as head of the civil engineering department at the University of Wisconsin, at Madison, Wis., having transferred there the previous year. His name was among the first ten appointments to the Stanford faculty, announced April 8, 1891; and that autumn he began a period of service as professor of civil engineering which was to last without interruption until his retirement as emeritus professor in 1923.

One of his earlier contributions to Stanford welfare was his professional advice in connection with the rebuilding of the University after the earthquake in 1906, when he was appointed on an engineering commission whose other members were William F. Durand and Prof. Charles B. Wing, M. Am. Soc. C. E. From 1917 until his retirement, Professor Marx served as acting president during the absences of President Ray Lyman Wilbur. He was executive head of the Civil Engineering Department, and a member of the advisory board and other university committees.

As early as 1896 Professor Marx was elected to the board of trustees of the City of Palo Alto. Thereafter, except for a break from 1904 to 1908, he held civic office until 1933, when he resigned from the chairmanship of the Board of Public Works, on which board he had held a position for twenty-four years. In 1898 when it was discovered that the city sewerage system installed under his supervision would not cost the full amount of the bond issue voted for the purpose, Professor Marx proposed that the remainder be used toward the inauguration of municipally-owned water and electric plants. It was due largely to his efforts that Palo Alto was also a pioneer among California cities in the operation of a municipal gas system; and through his guidance of the Board of Public Works, the Stanford engineer was responsible in a high degree for the economical development of the city's public works and utilities. Professor Marx was also prominent for many years in Palo Alto financial circles.

Professor Marx acted as consultant on a number of industrial and governmental projects. A list of the important engagements with approximate dates is as follows:

1893—consultant on the foundations of the San Francisco Ferry Building, in which he was assisted by Professor Wing;

1901—author of the report on Irrigation Problems in the Salinas Valley, California, published by the United States Department of Agriculture, Office of Experiment Station, Washington, D. C., as *Bulletin No. 100*;

1903—author of a report on the project of the Colorado Power and Irrigation Company at Denver, Colo.;

1904—author of a report on the St. Vrain Power Project, Colorado;

1906–1907—member, with Wynne Meredith and John D. Galloway, Members, Am. Soc. C. E., of the Board of Advisory Engineers on the Design of a Hydraulic Power Plant and Dams of the Stanislaus Power Company, later a part of the Pacific Gas and Electric Company;

1907—author of a study of the Buena Vista Pumping Plant of the San José Water Company;

1909—consultant to the Board of Directors of the Monterey County Water Works;

1912—chairman of the first State Water Commission, created on March 23, 1912, to administer the waters of California, and in this position Professor Marx assisted in framing the Water Laws of the state;

1912—associated with the late John R. Freeman,[3] Past-President and Hon. M. Am. Soc. C. E., in making early studies of water supply for the City of San Francisco, Calif.;

1913—consulting engineer to the City of Salinas, Calif., on the valuation of water and gas works owned by the Coast Valleys Gas and Electric Company;

1921–1923—consultant to the State of California in the preparation of *Bulletin No. 5,* "Flow in California Streams," and, in 1929–1931, of *Bulletin No. 28,* "Aspects of a Salt Water Barrier on Sacramento River";

1923—author of a report to the Board of Directors of Montecito Water District, Santa Barbara, Calif.;

1925–1926—member and chairman of the Board of Engineers, with G. B. Hegardt and Charles T. Leeds, Members, Am. Soc. C. E., of the Port of Oakland Harbor Development;

1926—member of the Peninsula Water Conference Committee;

1926—author of a study and report on the sewerage system of Reno, Nev.;

1927—member of the Board of Consulting Engineers, with F. H. Fowler and Charles H. Paul, Members, Am. Soc. C. E., of the San Gabriel Flood Control Board for the Los Angeles County Flood Control District;

1927—consultant to the San Diego Water Company;

1928–1929—member, with Mr. Paul, the late A. J. Wiley,[4] M. Am. Soc. C. E., and F. L. Ransome, geologist, of the Consulting Board to the East Bay Municipal District to investigate the causes of the partial failure of Lafayette Dam;

1929—member of the Engineering Commission on Sanitation and Drainage for the City of Oakland, Calif.;

1929—member of the Hoover-Young Commission that finally determined the location of the San Francisco-Oakland Bay Bridge across San Francisco Bay;

1930—adviser to the Public Works Engineering Corporation on the Chenery Reservoir, California;

1930—member of the San Francisco-Oakland Bay Bridge Advisory Committee of the San Francisco Real Estate Board;

1931—with C. F. Tolman, geologist, author of a geological and engineering report on the proposed dam at El Capitan Damsite No. 2 on the San Diego River to the City of San Diego;

1931—member, with J. B. Lippincott, Hon. M. Am. Soc. C. E., and John Buwalda, geologist, of the consulting board on Alterations and Improvements for Enlargement of the Chatsworth (Calif.) Reservoir;

---

[3] For memoir, see *Transactions,* Am. Soc. C. E., Vol. 98 (1933), p. 1471.

[4] For memoir, *loc. cit.,* Vol. 96 (1932), p. 1577.

1932, 1933–1935—member, with W. L. Huber, and F. C. Herrmann, Members, Am. Soc. C. E., as consultants to the State of California on the Bouquet Canyon Dam and the large earth and rockfill San Gabriel Dam No. 1. In 1932 Professor Marx was appointed Chairman of the Engineers' Advisory Board for the Reconstruction Finance Corporation, Washington, D. C. (in this capacity, he passed on such projects as the San Francisco-Oakland Bay Bridge, the bridge across the Mississippi River at New Orleans, La., the Colorado River Aqueduct of the Metropolitan Water District of Southern California, and numerous other projects throughout the United States);

1935—consulting engineer to the Metropolitan Water District of Southern California on the Design and Construction of the Cajalco Dam.

Professor Marx contributed several papers to the *Transactions* of the Society, including: "Experiments on the Flow of Water in the Six-Foot Steel and Wood Pipe Line of the Pioneer Electric Power Company at Ogden, Utah"[5] (with C. B. Wing, and the late Prof. L. M. Hoskins), and "Idealism and Art in Engineering."[6]

He was recipient of the honorary degree of Doctor of Laws (LL.D.) from the University of California in 1918 and that of Doctor of Engineering from the Karlsruhe Technische Hochschule in 1926. Professional affiliations and honors include: presidency of the American Society of Civil Engineers (1915) and Honorary Membership (1927); presidency of the San Francisco Section of the American Society of Civil Engineers; presidency of the Pacific Association of Consulting Engineers; presidency of the Joint Council of Engineering Societies in San Francisco; membership in the Western Society of Engineers, the Wisconsin Academy of Science; charter membership in the Society for the Promotion of Engineering Education; and chairmanship of the Arch Dam Committee of the Engineering Foundation. From 1926 to 1932 he was a member of the Executive Board of the American Civic Association. In 1929 he was a member of the American Committee to the World's Engineering Congress in Tokyo, Japan. In 1917 and 1918 he was a member of the Executive Committee on World Camp Community Service at Camp Frémont. In 1920, he was State Chairman of the National Public Works Department Association.

Professor Marx belonged to the Theta Delta Chi fraternity. His clubs included the Commonwealth Club of California (of which he was an honorary member and an early member of its committees on Water Resources and on Highways), the University Club, Menlo Country Club, and Monterey Peninsula Country Club.

In presenting Professor Marx to President John F. Stevens, Hon. M. Am. Soc. C. E., on the occasion when he was made an Honorary Member of the Society, Walter L. Huber said:

> "During these many years (at Stanford University) his influence has been felt not only by the hundreds of graduates of his own department,

---

[5] *Transactions*, Am. Soc. C. E., Vol. XL (1898), p. 471.

[6] *Loc. cit.*, Vol. LXXIX (1915), p. 1329.

> but by literally thousands of other young men, including even those who have graduated from rival institutions—it is a graduate of a rival institution who today presents him. With this record it is little wonder that throughout our country, and particularly through all of our western states, he has come to be affectionately known as 'Daddy Marx.'"

In 1888, Professor Marx was married to Harriet Elizabeth Grotecloss of Suffern, N. Y. Three children, Roland Grotecloss, Dorothy Grotecloss (Mrs. Edward B. Sherwood), and Alberta (Mrs. Harlan B. Granham), survive him; another daughter, Stephanie, died in her girlhood. Also surviving him are a brother, Guido Marx, and two sisters, Mrs. Frederick Will and Mrs. C. W. Curtis.

Public recognition of his contributions to the life of the University and the nation was afforded Professor Marx in his eightieth year when, in March, 1937, a campus luncheon in his honor was attended by active and emeritus members of the School of Engineering faculty. President Wilbur presided and stated that Professor Marx had built a place for himself in the affections of thousands of Stanford students, and had contributed to the solution of national engineering problems at Washington and on the Pacific Coast. This occasion was marked by the unveiling of a portrait of "Daddy" Marx painted by Mrs. Winifred Rieber of New York, N. Y., which had been commissioned by a group of Stanford graduates and which hangs in the Stanford Art Gallery.

"Daddy" Marx was best known through a long life as a great teacher who aroused in many generations of students a hunger for useful knowledge. He was sought out by many people from all walks of American life who needed the advice that he could give; and he gave freely and cheerfully of his store.

He had a keen sense of the dignity of the human race. Fellow engineers who accompanied him to China after an international meeting at Tokyo tell how he refused to ride in a jinrikisha because it exemplified inhuman toil.

"Daddy" left behind him a Stanford legend concerning his remarkable memory for facts and faces. It is said that after the first day of class work he could address any of his students by name, and recall personal incidents when meeting one of his acquaintance after many years. This habit of mind not only endeared him to students, but formed a personal bond of interest that made more effective his task as a teacher. His rugged geniality was a familiar part of campus life, and his spontaneous humanity inspired a ready response in everyone who knew him.

With the death of Charles David Marx, one of the last of the "Old Guard," passes a phase of Stanford history. The span of his service as a teacher comprised the origin and growth of Stanford University to its present place in the modern world; and not the least among those who were responsible for that growth was the beloved and dynamic man whom President Wilbur has termed "one of the real pillars of Stanford University."

Professor Marx was elected a Member of the American Society of Civil Engineers on October 7, 1896, and an Honorary Member on October 10, 1927.

GUSTAV LINDENTHAL, Hon. M. Am. Soc. C. E.[1]

DIED JULY 31, 1935

One of the gifted few among engineers who by technical genius combined with force of personality place a lasting impress on their art, Gustav Lindenthal was an acknowledged leader in the field of bridge construction for half a century. When he died at the age of 85, on July 31, 1935, he long had been the last remaining link between the present generation of civil engineers and the outstanding men of the nineteenth century.

His professional career extended from early engineering work in construction of the Centennial Exposition at Philadelphia, Pa., in 1876 to a commanding share in the development of modern bridge design during the 1880's and 1890's; later to construction of the Manhattan and Queensboro bridges as bridge commissioner of the City of New York, N. Y.; and still later to construction and execution of the world-famous Hell Gate arch and the Sciotoville continuous bridge. Perhaps the most dramatic element of his career was his 45 years of continuous effort to build a great railway suspension bridge across the Hudson River at New York.

Gustav Lindenthal was born in Brunn, Austria, on May 21, 1850, the son of Dominick and Franciska Schmutz Lindenthal. He was educated at Politechnicum (Dresden, Germany) College and received practical training from 1866 to 1870. He came to the United States in 1874, at a time of depression, and was forced to turn to handicraft for a livelihood, working for some months as a stone-mason on the Memorial Hall at the Centennial Exposition, then being built. In the course of this work, however, the engineers in charge of Exposition construction recognized his ability and transferred him to designing. Soon he was in charge of the two permanent buildings, Memorial Hall and Horticultural Hall, both still standing in Fairmount Park. When Exposition construction came to an end he obtained a position with the Keystone Bridge Company of Pittsburgh, Pa., as computer and designer.

In 1878 he was appointed bridge engineer of the Atlantic-Great Western Railroad at Cleveland, Ohio. Rebuilding many of the early structures of that railway further developed his technical skill, and his association with outstanding railway engineers, the late Charles Latimer[2] and Arthur Mellen Wellington,[3] Members, Am. Soc. C. E., chief among them, increased the breadth of view and determination that characterized him throughout his life.

In 1881 Mr. Lindenthal took up private engineering practice in Pittsburgh, and soon found himself in charge of the design and construction of important bridges for railroads and bridge companies. His earliest major structure was the Smithfield Street bridge over the Monongahela River[4] built in 1882, replacing a suspension bridge built by the late John A. Roebling, M. Am. Soc. C. E. It was distinguished both by the novelty of its double-elliptical trusses of 350-ft span and by the use in parts of the structure of steel, then new in bridge construction. He also built the Allegheny River bridge at Seventh Street, Pittsburgh, a four-span continuous suspension bridge with double-braced eyebar chains. Other important works were continuous bridges at McKeesport and at Herr's Island. The originality and boldness of conception of all these structures, their excellent adaptation to the site and service, and their striking appearance ranked him at once among the leading bridge engineers of his day.

---

[1] Memoir prepared by F. H. Frankland and F. E. Schmitt, Members, Am. Soc. C. E.

[2] For memoir, see *Proceedings*, Am. Soc. C. E., Vol. XV–XVI (1889–90), p. 137.

[3] For memoir, *loc. cit.*, Vol. XXI (1895), p. 199.

[4] For description, see *Transactions*, Am. Soc. C. E., Vol. XII (1883), p. 353.

In the late eighties the desire of the Pennsylvania Railroad to obtain direct rail entrance into New York City brought Mr. Lindenthal into close contact with the late Samuel Rea, Hon. M. Am. Soc. C. E., and with the problems of bridging the Hudson River and the waters between Long Island and the Bronx mainland. Pres. George B. Roberts instructed Mr. Rea to "find the best bridge engineer you can hire," and Mr. Rea, who had known of Mr. Lindenthal's unusual bridge operations in Pittsburgh, called on him to advise the company.

The plan for a New York entrance first centered around a proposed terminal at Washington Square, but the cost of such an entrance for the Pennsylvania alone appeared excessive. Mr. Lindenthal was commissioned to learn the attitude of the other railroads on participating in the bridge; the outcome was the formation in 1890 of the North River Bridge Company, whose incorporators included Thomas F. Ryan, financier, and Garrett V. Hobart, later Vice-President of the United States. A federal charter was obtained, and the company proceeded energetically to develop plans for the bridge. However, litigation delayed the beginning of field operations, and just as this was successfully terminated the business depression of 1893 forced indefinite postponement of the project.

Although brought to a halt, the enterprise gave rise to a memorable engineering investigation. In preparing to pass on the North River Bridge Company's application for a permit to build the bridge, the War Department, in 1894, appointed a board of engineers to advise concerning the feasibility of this and two other bridge projects also involving spans of unprecedented length—Mr. Lindenthal's proposed bridge having the unheard-of span length of 3,100 ft. This board made two reports, the first as to the maximum span practicable for suspension bridges and the other on the length of span most suitable for a bridge between Fifty-Ninth and Sixty-Ninth Streets, New York City. The first report determined 4,335 ft as the longest practicable suspension span, and the second report stated that a minimum span of 2,000 ft was required at the designated locations and that it was practicable to build a span of 3,100 ft as proposed by Mr. Lindenthal.

For a decade the Hudson River crossing remained dormant. Finally in 1904 the Pennsylvania Railroad, on finding that the other roads were reluctant to join, decided on a tunnel entrance to New York. Mr. Lindenthal was named a member of the board of engineers to direct the tunnel and terminal undertaking, and the bridge was again relegated to a distant future.

Mr. Lindenthal did not give up the Hudson River bridge project but revised his plans to suit the rapidly progressing northward movement of population and trade in the city. He had, in the early nineties, first chosen a new site at 23d Street, and after the World War, another still farther north, at 57th Street, with associated plans for a crosstown highway connection and its extension to the Long Island bank by the Queensboro Bridge, afterward modified to suit a proposed two-span arch bridge crossing at Fifty-Seventh Street.

Meantime, he was enlisted in the solution of other large bridge problems as Bridge Commissioner of New York City in 1902–1903. Growth of traffic between Long Island and Manhattan demanded two new East River bridges, one adjacent to the Brooklyn Bridge, the other some miles north at Blackwells (Welfare Island), later named Manhattan and Queensboro bridges. They offered prime opportunity for bold conception. Mr. Lindenthal first planned an eyebar chain suspension bridge with rocker towers for the 1,470-ft span of the Manhattan Bridge; in the following administration this design was transformed into a wire-cable design with fixed-base cellular plate columns as towers, a model for most large suspension bridges of later years. For the shorter spans of the Queensboro Bridge, crossing two separate channels over an island, he designed a double cantilever without suspended spans, and this design was adopted.

For probably the first time in American bridge history an architect was called in to collaborate on the design of these two structures—because of Mr. Lindenthal's conviction that a major bridge should be distinguished by good appearance as well as by strength and traffic capacity.

Soon after Mr. Lindenthal's service as bridge commissioner he was entrusted with the exceptionally important and difficult task of connecting the Pennsylvania-Long Island trackage with the New York, New Haven and Hartford Railroad in the northern part of the city by a bridge and viaduct crossing Hell Gate. In general location this connection had been projected years before by Mr. Rea and Mr. Lindenthal, when studying the New York entrance problem. Mr. Lindenthal was appointed chief engineer of the New York Connecting Railroad, and it engaged nearly all his energies for ten years, from 1907 to 1917.

Hell Gate arch was the most notable element of this enterprise. Its span of nearly a thousand feet, its four-track deck with ballasted concrete trough floor, the unprecedented size and weight of its members, and above all its striking outline, justly made it the best-known bridge of its time.

Before Hell Gate was completed, the Norfolk and Western Railroad required a bridge across the Ohio River to connect its main line with routes to Cincinnati, Ohio, Columbus, Ohio, and Chicago, Ill. The selected site, a few miles east of Sciotoville, Ohio, presented a river width of more than 2,000 ft and the requirement of two navigation channels. From 1914 to 1917, Mr. Lindenthal built a two-span structure 1,550 ft long, continuous over a central pier; it remains perhaps the boldest continuous bridge in existence.

After the World War, the desirability of bringing the New Jersey railroads, other than the Pennsylvania, into New York City again came to the fore. The lines joined in forming a committee of chief engineers under the chairmanship of the late John F. Wallace,[5] Past-President, Am. Soc. C. E., to develop a comprehensive scheme for efficient freight and passenger handling by way of Mr. Lindenthal's projected Fifty-Seventh Street. Mr. Wallace died in 1921, and the late Francis Lee Stuart,[6] Past-President, Am. Soc. C. E., joined in the work as vice-president and consulting engineer of the North River Bridge Company, Mr. Lindenthal being president and chief engineer. Agreement was reached on all major elements of the project, and in 1922, when working plans were well advanced, application for a permit was made to the War Department by the Bridge Company. It was not until 1928 that the department acted, however, and then it rejected the application on the ground of insufficient clearance height. Revised plans were developed to meet the clearance limits stipulated, but in 1931 these plans were again rejected, this time on the ground that no bridge should be built at the site proposed. Mr. Lindenthal was active in attempting to overcome the objections of the War Department to the Fifty-Seventh Street site until his work was taken over, to a great extent, by others a few years before his death.

In 1928 he had completed his last major bridge enterprise, which was the design and construction of a group of large bridges in Portland to carry the city's principal thoroughfares across the Willamette River. These structures are among the noteworthy engineering monuments of that city.

It was often said of Mr. Lindenthal during his lifetime, and with truth, that he never built two bridges alike. In this fact lies the best expression of his habit of looking on each bridge problem as new and unique, a problem whose proper solution could hardly be the same as that of any prior bridge problem. Moreover, he took up each bridge project broadly, seeking first a conception of general form that would offer the best solution and going on to stresses and details only as the last step. A gift of creative originality was obviously essential for such procedure, and this gift he possessed in high degree. Often his designs required the invention of new details, and he was never at a loss for an answer to such demands.

An innate love of beauty in engineering works went hand in hand with this seeking for the structurally best form. In part it seemed to spring from a conviction that a form satisfying the eye will also satisfy the demands of strength. In part, however, it reflected an esthetic sense that impelled him to seek the aid of men specially qualified in esthetic design whenever he had to deal with an important bridge project.

Throughout much of his career Mr. Lindenthal was a strong advocate of eyebar chains in place of wire cables as main carrying members of suspension bridges. His early success with the Seventh Street Bridge at Pittsburgh gave him assurance of the practicability and economy of such construction, and his design for the Manhattan Bridge contemplated the use of eyebar chains as has been mentioned. The precedent of the Brooklyn, Niagara, and other major wire-cable bridges was sufficiently strong to prevent the wide use of chains; nevertheless Mr. Lindenthal's views were a contributing influence in the successful development of high-strength, heat-treated eyebars by the American Bridge Company some 20 years ago.

---

[5] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1635.

[6] For memoir, *loc. cit.*, Vol. 101 (1936), p. 1493.

Mr. Lindenthal's bridge work was at all times his major preoccupation. He found time, however, to deal with other important problems, some of them later made the subject matter of papers which he presented before engineering societies, while others were embodied only in private reports to his clients. His study of the curve-resistance of railway cars and the design of rocker side bearings to reduce this resistance, and a study of an inverted U-rail to replace the standard T-rail in order to assure better metallurgy and structure of the steel, were among his more important investigations. His active mind also carried him outside the field of engineering problems, and he interested himself in many scientific and public matters.

Gustav Lindenthal contributed a number of important papers to the American Society of Civil Engineers and other engineering organizations, but throughout his life was too active to find the leisure necessary for writing books. His abilities and achievements were recognized by many distinctions conferred on him in the course of his career, including honorary degrees given him by a number of universities.

Nature had endowed Mr. Lindenthal with a powerful frame as impressive as his forceful and magnetic personality; but although he enjoyed robust health during most of his life, he had to undergo a series of severe operations after he had passed the age of 80. He never recovered fully from their effects, and passed away at his Metuchen home on July 31, 1935, in his 86th year. A more complete memoir is filed, for reference, in Engineering Societies Library.[7]

In 1902 he was married to Gertrude Weil of New York, who died in 1905. In 1910 he was married to Carrie Herndon of Durham, N. C., who survives him together with a daughter, Franciska Lindenthal.

Mr. Lindenthal was elected a Member of the American Society of Civil Engineers on May 3, 1882, and an Honorary Member on October 7, 1929.

HENRY BISSELL ALVORD, M. Am. Soc. C. E.[1]

DIED APRIL 20, 1939

The life of Henry B. Alvord was a remarkably full and fruitful one, notwithstanding the fact that it fell some sixteen years short of the allotted three score years and ten. In this relatively short span of time, he was able to encompass not only substantial achievements in his professional field of civil engineering but also a great variety of other accomplishments which gave to his personality a symmetry and charm far from common. Father of a very happy family of four children—two sons and two daughters—Henry Alvord drew a rich and satisfying enjoyment from his family life and responsibilities, which reflected itself in his personal philosophy and manner.

---

[7] 29 West 39th Street, New York, N. Y.

[1] Memoir prepared by E. A. Gramstorff, Assoc. M. Am. Soc. C. E.

From a long line of sturdy forbears reaching back three hundred years to Alexander Alford (name later changed to Alvord), of County Dorset, England (who settled in Northampton, Mass., in 1640), Henry Alvord inherited the vigorous traditions of New England pioneers. His father, Henry Clay Alvord, of Bolton, Conn., was educated for the Congregational ministry at New York University in New York, N. Y. His mother—née Alice Bissell—of Charlemont, Mass., came of a family originally located in Wilmington, Vt.

During the first pastorate of the Rev. Henry Clay Alvord, at Montague, Mass., a son was born on March 24, 1885, and christened Henry Bissell Alvord. When the boy was but a year old, his father accepted a call to the Old South Congregational Church in South Weymouth, Mass., where he served continuously until his death thirty-three years later.

Young Henry B. Alvord was educated in the public schools of Weymouth, Mass., from which he entered the Massachusetts Institute of Technology, at Cambridge, Mass., to study civil engineering. He was graduated from the Institute in 1907 but remained for three subsequent years as an assistant in the Department of Civil Engineering. During the summer months of the latter period, he was employed by the Commonwealth of Massachusetts for the purpose of establishing town boundaries and the geodetic position of their corners. In this work he showed a very high regard for precision and accuracy in his measurements. It was probably through this experience that he developed the keen interest in geodetic matters which remained with him throughout his life.

In the course of these summer assignments, he met, and later married at Bethlehem, N. H., Margaret Graham, daughter of John Graham from Langholm, Scotland, a Congregational minister who held various pastorates throughout New England.

Following his marriage, Mr. Alvord accepted a position as instructor in civil engineering at Bowdoin College, in Brunswick, Me., was made assistant professor the following year, and served continuously in this position until June, 1914, when he left the field of teaching to gain further professional experience. He served first as office assistant and librarian for the Aberthaw Construction Company, leaving their employ in March, 1918, to accept an appointment as chief of party with the county engineer in Braintree, Mass.

In 1919 he returned to teaching at Wentworth Institute in Boston, Mass., but after one year resigned to become assistant professor of civil engineering at Northeastern University, in Boston, in September, 1920. A year later he was made professor of civil engineering and chairman of the department, a position which he filled continuously thereafter until his death.

During nearly two decades in which he led the Department of Civil Engineering, Professor Alvord left the impress of his personality upon many hundreds of engineering students. He helped the College of Engineering grow from a very small, struggling institution to one that was strong, sound, and adequately housed. Throughout his service on the faculty, Professor Alvord was always eager to cooperate with other members of the staff in improving the work of the college. He had a genuine and unflagging interest in student activities, as well as in the professional aspects of instruction. Always a lover of the outdoors, and a particularly capable tennis player, he was able to meet students on their own ground outside of the classroom. One of his special hobbies was the planning of inspection trips and expeditions upon which faculty and students could mingle in friendly social intercourse.

In the course of his long teaching experience, Professor Alvord taught most of the subjects that are given in an undergraduate curriculum in civil engineering, but for the last decade of his life he concentrated his effort largely in the field of engineering structures.

During summer vacation periods he worked on various engineering jobs. At one time he served the Great Northern Railway Company in full charge of the triangulation survey for the Cascade Tunnel, and, at another time, he completed a triangulation of the City of North Adams, Mass. In the summer of 1923–1924 he served as instructor at the Harvard Summer Camp at Squam Lake, N. H.

He was a member of the American Concrete Institute and served as its secretary from 1917 to 1920. Other technical societies with which he was associated are the Boston Society of Civil Engineers (of which, at the time of his death, he was a director and faculty advisor of the student chapter at Northeastern University); the Society for the Promotion of Engineering Education; and the Massachusetts Federation of Planning Boards, of which he was secretary for two years and treasurer at the time of his death. He also served as a member of the Planning Board of the City of Melrose, Mass., from 1931 to 1934.

As a young man he studied the piano at the New England Conservatory of Music under Charles Dennee, and, together with his wife, thoroughly enjoyed a great interest in and love for music throughout his life. Both Professor and Mrs. Alvord were active members of the Beethoven Club of Melrose, of which he was a past-president. He developed (particularly in his later years) a whole-hearted interest in social, political, and economic problems, and was active in municipal and church affairs.

Professor Alvord is survived by his wife and four children, Margaret (Mrs. R. L. Briggs), John R., Graham G., and Jean Ruth.

Professor Alvord was elected an Associate Member of the American Society of Civil Engineers on June 6, 1927, and a Member on August 15, 1938.

JAMES MACFARLANE ANGLE, M. Am. Soc. C. E.[1]

DIED OCTOBER 30, 1939

James Macfarlane Angle was the eldest of four children, two boys and two girls, born to E. J. and Mary Clymer (Macfarlane) Angle. He was born in

---

[1] Memoir prepared by a Committee of the Alabama Section composed of J. L. Land, M. Am. Soc. C. E., and H. C. Wells, Assoc. M. Am. Soc. C. E.

Towanda, Pa., on September 15, 1884. As a youth, Mr. Angle attended the public and high schools of Towanda, later going to Bingham Military School at Asheville, N. C., for a year. He attended the Virginia Military Institute at Lexington, Va., for two years, and later completed his professional education by a 4-yr course at The Pennsylvania State College, at State College, Pa., from which he received the degrees of Bachelor of Science in Engineering in 1910 and Civil Engineer in 1923.

Almost immediately after graduation he began work in the engineering field. He served the Pennsylvania Steel Company, in Steelton, Pa., as draftsman until 1911, the U. S. Reclamation Service on the Flathead Project in Montana as rodman and instrumentman during 1911, the Great Northern Railway Company in the State of Washington as chairman and inspector in 1912, and the Northern Pacific Railway Company in the State of Washington as inspector on timber and concrete construction during 1913.

In April, 1914, Mr. Angle was employed by the Allegheny County (Pennsylvania) Engineering Office of Pittsburgh, and served as draftsman and inspector on the construction of bridges. He also assisted in making road and bridge locations and plans until he entered the U. S. Army in October, 1917.

Mr. Angle's services in the U. S. Army date from October, 1917, until April, 1919. He was commissioned a First Lieutenant and experienced various phases of army engineering, such as directing, mapping, and railway construction with the 45th Engineers; and Company Commander and Personnel Adjutant, 545th Engineers. He went overseas with the 545th Engineers in September, 1918, contracted influenza and other ailments immediately after landing, and was soon sent back to the United States for treatment. He was honorably discharged from the Army in April, 1919.

He then returned to the Allegheny County Engineering Office and served there until November, 1919, at which time he went with Morris Knowles, Incorporated, of Pittsburgh and served as computer on sewer system investigation until September, 1920.

In November, 1922, he entered the service of the U. S. Bureau of Public Roads and was connected with this office until his death in October, 1939. While with the Bureau of Public Roads, Mr. Angle climbed steadily from an associate highway bridge engineer to highway bridge engineer and senior highway bridge engineer. His responsibilities increased from checking and designing to district bridge engineer, which covered both designs and construction for the 8th District of the Bureau of Public Roads.

Mr. Angle's wide range of experience in diversified work gave him a well-rounded knowledge of the engineering field, and he was considered an authority on movable bridge spans. He was also interested in the profession as a whole, and built up quite a collection of engineering books, which he donated to the Montgomery (Ala.) Engineers' Club before leaving Montgomery.

His retiring disposition won him many close and confidential friends, but did not reveal the intellect of the individual to the extent that he deserved. In addition to his career as an engineer, he was a Mason, a member of the Presbyterian Church, a gentleman of the highest type, and an honor to the engineering profession and the community in which he lived.

Mr. Angle died at the residence of a sister in Pittsburgh on October 30, 1939. He was buried in the family cemetery at Towanda, and is survived by his aged mother; a brother, Philip E. Angle; and two sisters, Mrs. Guy F. Batchelor and Mrs. Thomas W. Oberhauser.

Mr. Angle was elected an Associate Member of the American Society of Civil Engineers on January 17, 1921, and a Member on July 12, 1937.

WILLIAM JOHN ASH, M. Am. Soc. C. E.[1]

DIED JULY 10, 1939

William John Ash was born in New York, N. Y., on April 27, 1884, the son of William Robert and Ernestine J. Ash. He received his early education in the public schools, and was graduated from Cooper Union, in New York, in 1909, with the degree of Bachelor of Science. In 1913, he received the degree of Civil Engineer from the same institution.

From November, 1905, to February, 1907, he acted as rodman and inspector of construction for the New York Central Railroad Company at Yonkers, N. Y. In February, 1907, he secured a position with the Bureau of Engineers at New Brighton, N. Y., first as draftsman and designer, and then as assistant chief draftsman of the construction division, on design and supervision of various municipal improvements.

From August, 1914, to November, 1917, Mr. Ash was with the Public Service Commission as assistant engineer. During the latter part of this time he was in charge of field and office work, as assistant to the section engineer.

In November, 1917, he became associated with the Air Nitrates Corporation in New York, first as squad leader on U. S. Nitrate Plant No. 2, at Muscle Shoals, Ala., and then, after July, 1918, as assistant engineer of designs on U. S. Nitrate Plants Nos. 3 and 4. In December, 1918, he left the Air Nitrates Corporation to become civil and mechanical engineer for the American Cyanamid Company. Among other things, he directed the design of buildings.

From December, 1919, to May, 1920, Mr. Ash was with the Central Dyestuff and Chemical Company, in Newark, N. J., as designing engineer in charge of building alterations, installation of chemical plant equipment, etc. He returned to the American Cyanamid Company in May, 1920, and was in charge of designs of chemical plant equipment and construction.

From August, 1921, to October, 1922, he was with M. Shapiro and Sons, in New York, as civil and structural engineer, designing steel buildings and foundations, and was also in charge as superintendent on reservoir construction at Liberty, N. Y., for the Workmen's Circle Sanitarium.

---

[1] Memoir prepared by R. de C. Greene, Esq., New York, N. Y.

In October, 1922, he again returned to the American Cyanamid Company, this time as chief draftsman in charge of design of buildings and chemical plant equipment, drawing up specifications, etc. He was with this company until his death, with the exception of a period in 1923, when he acted as consulting engineer for the Warner Chemical Company, at Carteret, N. J., on building changes.

Mr. Ash was a member of Excelsior Lodge, Free and Accepted Masons 195, in New York, Modern Woodmen of America, Manhattan Camp 11578, and Sigma Alpha Pi Fraternity.

He was married on October 19, 1910, to Anna Sheffield, who, with one son, William, survives him.

Mr. Ash was full of energy and enthusiasm. Even at the outset of his engineering career, he was distinguished by the same qualities that later made him a valued man in directing the important design work of the Air Nitrates Corporation, in the construction of the Muscle Shoals plant during the World War, and his subsequent activities with the parent company.

His good humor was characteristic and his enjoyment of his work contagious. He was studious and developed himself to cover other fields of engineering in addition to the structural work in which he was so well grounded. He had many friends, was always ready to be of service, and his was a life full of endeavor, accomplishment, and courage.

Mr. Ash was elected an Associate Member of the American Society of Civil Engineers on November 25, 1919, and a Member on October 21, 1924.

CALVIN LEWIS BARTON, M. Am. Soc. C. E.[1]

DIED MAY 10, 1939

Calvin Lewis Barton was born in Little Meadows, Pa., on May 16, 1874, the son of Lewis William and Caroline (Beebe) Barton. On both the paternal and maternal sides, his ancestors were among the earliest colonial settlers, one of them being William Bradford, first Governor of the Plymouth (Mass.) Colony.

After his preparatory education at Cazenovia Seminary, Cazenovia, N. Y., Mr. Barton entered Cornell University at Ithaca, N. Y., and was graduated, in 1899, with the degree of Civil Engineer. During his University years, he not only participated in extra-curricular activities, but prepared the tables for "The Transition Curve" by the late Charles Lee Crandall, M. Am. Soc. C. E. Later he was active in alumni affairs, especially those of the Cornell Society of Civil Engineers.

Upon graduation from Cornell, Mr. Barton entered the employ of the Rochester Bridge and Iron Works and, upon the formation of the American Bridge Company, worked at their Pencoyd Plant.

In 1901 he was employed by the late Ira A. Shaler, M. Am. Soc. C. E., on the Park Avenue tunnel section of the original New York subway, and remained on this work until its completion in 1904. He was then employed by S. Pearson and Son on compressed air equipment and caissons for the Pennsylvania Railroad, East River Tunnels, and later acted as General Superintendent for the Phoenix Construction Company on the driving of an experimental tunnel for the Pennsylvania, New York and Long Island Railroad Company.

---

[1] Memoir prepared by Glenn B. Woodruff and Charles E. Fraser, Members, Am. Soc. C. E.

In 1906 Mr. Barton joined Leslie McHarg, Assoc. M. Am. Soc. C. E., and formed the McHarg-Barton Company. Until the dissolution of the firm in 1928, this Company specialized in bridge and harbor construction. Among their larger contracts were Chelsea Pier No. 53 for New York, N. Y., and two of the Stapleton Pier Sheds on Staten Island, New York; Warehouses at Fort Monroe and Charlestown Navy Yard; foundations for the Statue of Liberty; and bridges over the Saugatuck River at Westport, Conn., and the Norwalk River at Norwalk, Conn.

In 1928 Mr. Barton became associated with the Fraser-Brace Engineering Company, Inc., of Montreal, Que., Canada, and New York, in the capacity of Cost Engineer on the New England Power Dam of the 15 Mile Falls hydro-electric power development near St. Johnsbury, Vt. Upon completion of this work in 1930, he established a consulting practice at Norwalk and also devoted part of his time to business interests there, being associated with the Norwalk Savings Society.

During the latter part of his life, Mr. Barton devoted much of his time to civic affairs. He was elected Mayor of Norwalk in 1921 and served two terms. Later he served as a member of the Board of Public Safety and was active in the affairs of the Young Men's Christian Association, serving as its President from 1935 to 1938. In 1938 he was selected to serve on the special grand jury which investigated the Schuyler Merritt Parkway land purchases.

Mr. Barton was a member of the Sigma Xi and Tau Beta Pi fraternities, the Connecticut Society of Civil Engineers (Director from Fairfield County for one term), St. John's Lodge, F. and A. M., the Norwalk Country Club, and the Congregational Church of Norwalk.

In 1908 he was married to Nina Bagley, who, with one son, Bradford, survives him.

Mr. Barton was elected an Associate Member of the American Society of Civil Engineers on April 4, 1906, and a Member on May 6, 1914.

GEORGE ERLE BEGGS, M. Am. Soc. C. E.[1]

DIED NOVEMBER 23, 1939

George Erle Beggs was born in Ashland, Ill., on April 23, 1883. His father and mother, Charles Edwin Beggs and Emma Beggs, were cousins. Edwin

---

[1] Memoir prepared by Carlton S. Proctor, M. Am. Soc. C. E., Elmer K. Timby, Assoc. M. Am. Soc. C. E., Arthur M. Greene, Jr., Dean, School of Eng., and Professor of Mechanical Eng., Princeton Univ., Princeton, N. J., and Kenneth H. Condit, Cons. Editor of *American Machinist* and *Product Engineering*, McGraw-Hill Book Co., Inc., New York, N. Y.

Beggs, as he was known, was a large grain dealer and owned extensive farm lands in Illinois and in the Canadian prairie provinces.

After being graduated from the high school at Ashland, George Beggs matriculated at Northwestern University, at Evanston, Ill., and was graduated with the Bachelor of Arts degree in 1905. He was elected to Phi Beta Kappa at Northwestern. For his engineering education he went to Columbia University, at New York, N. Y., where he was graduated with highest honors in civil engineering in 1910, receiving the Illig Medal. While at Columbia, Mr. Beggs was elected to Tau Beta Pi and Sigma Xi fraternities. During two of his summer vacations he served as instructor in field surveying and geology at the Columbia summer camp near Litchfield, Conn.

For two years after leaving Columbia, Mr. Beggs worked for the American Bridge Company as a draftsman and checker of stress sheets. Here he did his first analysis of stresses in indeterminate structures in which field he was destined to earn distinction. He calculated the erection stresses and deflections of the Bessemer and Lake Erie Railroad bridge, a double-track, indeterminate structure 2,000 ft long, continuous over three spans, and costing about $1,000,000. He also made the design calculations for the Quachee Railway arch near Hanover, N. H.

About this time Union College called on the American Bridge Company for temporary aid in the conduct of courses in kinematics, theoretical mechanics, and surveying, and Mr. Beggs was assigned to the task. Later, he spent four months with Falk and Hager of New York City, consulting engineers, on the design of steel frame buildings, and six months on the Lehigh Valley Railroad valuation survey. He then accepted a position as chief engineer of the Phosphate Mining Company near Lakeland, Fla., and spent nearly two years with that organization on design and construction work.

In 1914 Mr. Beggs was called to Princeton University, at Princeton, N. J., to teach applied mechanics, advanced structures, and mechanics of materials. He was made an assistant professor of civil engineering in 1915, associate professor in 1921, and professor in 1930. In 1921 he became Secretary of the School of Engineering, and was appointed chairman of the Department of Civil Engineering in 1937.

Professor Beggs' special interest was in the field of indeterminate structures. His studies eventually led to his invention of the method of analyzing such structures by means of elastic scale models and the Beggs Deformeter Gauge on which he obtained a patent. He was also granted a patent on a slide-rule bomb sight for airplanes during the World War, and on a pressure control valve in 1939.

After developing the method of analyzing models of structures which could be deformed in two dimensions, Professor Beggs proceeded to apply his methods to three-dimensional analysis, first to a model of a skew concrete arch and then to a model of a concrete arched dam. The investigation of the latter structure, which was a model of the experimental Stevenson Creek Concrete Dam, gave valuable conclusions regarding deflections which were not shown by the experimental dam because of lack of uniformity in the concrete, and were not included in the mathematical analysis because of incorrect assumptions. The stress distribution in general was similar to that from the dam. This investigation demonstrated the applicability of accurate model analysis to such structures with a resulting saving in expense of considerable importance. The experimental dam cost more than $100,000, the model less than $500.

Another pioneering job was the application of model tests in providing the influence lines for the design of the foundations for the Albany (N. Y.) Bell Telephone Building, the first foundation ever designed utilizing the principle of the Vierendeel truss for the distribution of structural loads through a thin slab after excavation of soil materials approximating the weight of the structure to be supported. Although an enormous amount of work on such treatment of foundations has been done since this job, the Albany Telephone Building still stands as a model for foundation treatment of soft and relatively unconsolidated residual clay deposits, and the description of this job together with the important part played by Professor Beggs in his model analyses of a thoroughly indeterminate structure has been translated into every modern language.

Next came the analysis of the stresses in members of suspension bridges by the model method. The first check analysis on the model of an existing bridge on which an intricate mathematical analysis had been made indicated a discrepancy which turned out to be the result of an error in the mathematics. This demonstration of the reliability of the method resulted in the employment of Professor Beggs for a similar analysis of the San Francisco-Oakland Bay suspension bridge for the California Department of Highways.

Somewhat later Professor Beggs was retained to make a model analysis of the towers for the Golden Gate Bridge. Entirely new principles of design had been developed for these towers. The soundness of these principles was demonstrated by the model tests. His last extensive investigation of this kind was for the United States Navy. The model used was a stainless steel type model of a floating structure with a maximum dimension of more than 1,000 ft. In addition to the foregoing investigations, Professor Beggs was frequently consulted by engineers, architects, and manufacturers on structural problems.

In the years 1923, 1926, and 1934, Professor Beggs traveled widely in Europe investigating engineering projects and visiting technical schools. Lectures on his method of analyzing indeterminate structures were given before a conference of the Academy of Sciences in Zurich, Switzerland, in Paris, France, and before engineering conferences in other continental cities.

Professor Beggs was a consultant on the design of the Goodyear-Zeppelin hangar at Akron, Ohio, with special reference to laying out the program for deflections and stresses to allow for expansion and contraction of the structure. He investigated the failure of the Hackensack Bridge and was special consultant for the Raritan River Bridge. He also assisted the Taylor Wharton Iron and Steel Company in developing high tensile steel for railway track work.

Two medals, in addition to the Illig Medal, were awarded to Professor Beggs for his research achievements—the Wason Medal, by the American Concrete Institute, in 1922; and the Howard N. Potts Medal, by the Franklin Institute, in Philadelphia, Pa., in 1927. He was the author of the following technical books and articles: "Live Load Stresses in Railway Bridges," later translated into Spanish; "Mechanical Solution of Indeterminate Structures," American Concrete Institute, later translated into French, German, Spanish, and Russian; "Experimental Design of a Multiple-Arch System and Permissible Simplifications," discussion in *Transactions*, Am. Soc. C. E.[2]; "The Use of Models in the Solution of Indeterminate Structures," *Journal* of the Franklin Institute; "Tests on Structural Models of Proposed San Francisco-Oakland Suspension Bridge"; "Skew Arch Reactions Measured by the Reciprocal Method," *Engineering News-Record;* "Suspension Bridge Stresses Determined by Models," *Engineering News-Record.*

In the course of his professional career Professor Beggs was active in the work of the Society, serving as member and chairman of several important committees. He was also a member of the council of the American Institute of Consulting Engineers, and chairman of the Engineering Foundation.

Professor Beggs entered generously into the social life of the Princeton faculty and of the town community, and he contributed his aid freely to many worthy causes. The minutes of the Princeton faculty regarding his death read: "Not only Princeton University but the Borough of Princeton as well will long remember his kindly life and service extending over a quarter of a century."

Professor Beggs was married to Frances May Ingalls of New York in 1912. He is survived by his widow and their only child, George Erle Beggs, Jr.

Professor Beggs was elected a Junior of the American Society of Civil Engineers on October 3, 1911; an Associate Member on September 2, 1914; and a Member on April 16, 1923.

JAMES C. BELL, M. Am. Soc. C. E.[1]

DIED JUNE 10, 1939

James C. Bell was born in Albany, N. Y., on November 24, 1883, the son of the late James C. Bell, M. Am. Soc. C. E., and Anna (Talcott) Bell. His paternal grandmother was of the Pruyn family of Albany, and his father was of the Bell family who were in business in Newport, R. I., in 1768. His father was also a civil engineer and was graduated from Union College, at Schenectady, N. Y., in the class of 1868.

Mr. Bell attended the old Albany High School and Rensselaer Polytechnic Institute, at Troy, N. Y., where he was graduated in 1906 with the degree of Civil Engineer. He was a member of Sigma Xi and the Rensselaer Society of Civil Engineers.

---

[2] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 1208.

[1] Memoir prepared by Albert R. Reilly, M. Am. Soc. C. E.

During summer vacations while in college and until January, 1908, "Jim" or "Tinkle," as he was known to his many friends, worked his way up from axman to chainman, rodman, and instrumentman in charge of construction and of survey parties with the State Engineer's Department, Division of Highways.

From January, 1908, until September, 1918, he worked up from assistant engineer to resident engineer on many dams, locks, bridges, hydraulic surveys, and designs of the Barge Canal Division of the state engineer's office. Some of the projects were: Dam No. 2 at Crescent, N. Y.; Dam No. 4 at Scotia, N. Y.; Dam No. 3 at Vischer Ferry, N. Y.; Crescent Highway Bridge over the Mohawk River; Vischer's Ferry Viaduct; Freman's Bridge over the Mohawk River; and surveys and studies of lower Hudson River terminals.

Jim Bell had charge of the preliminary survey for Storm King Highway and the first road between McKeever and Old Forge in the Adirondack Mountains, New York. The largest and finest monument standing to James C. Bell's memory, however, is a very unique structure, The Western Gateway Bridge, of twenty-four reinforced-concrete spans built on a curve over the Mohawk River at Schenectady. From September, 1918, to January, 1924, Jim with his assistants and the contractors labored most earnestly to produce the $3,000,000 structure.

In January, 1924, he was appointed commissioner of public works of Schenectady by Mayor William W. Campbell on the recommendation of the late Frank M. Williams,[2] M. Am. Soc. C. E., state engineer. He held this position until January, 1926, when, for a month, he acted as consultant on claim work for the state engineer.

From February, 1926, until June, 1939, he was construction engineer for the Board of Education of Rochester, N. Y., and was in charge of field supervision of the construction of many school buildings, the most outstanding being Charlotte High School and John Marshall High School.

It is most fortunate that occasionally a man is born to this world who can be an inspiration to his fellow men; one who can smile and make others smile, even on those dark days; one whom every one is glad to see and meet, even for only a few words; one who is a welcome friend at any gathering; one whom all men trust and respect and who is so genuinely loyal that he can be rated as a man among men; a man who likes his work well enough to do it thoroughly and who never tires of it enough to spoil his ambition to learn to do it better each time; a man who loves his family genuinely and his neighbor well enough to be every-ready with a helping hand and the kind word; and one who has a true sense of humor, wit, and the gentlemanly instinct to use it properly so that he is envied and loved by all. All of these qualities and more were possessed by Jim Bell, as all affectionately called him. When he passed on, although it was felt that he had gone to a just and well-earned reward, every one felt that the world could ill spare him, that the world needed more like him, and that the profession of engineering had really gained by his membership and record.

James C. Bell was married to Jane Davidson on September 3, 1908. He is survived by his widow; their twin sons, James C. and Gordon R.; and a brother, Roy W. Bell.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1626.

Mr. Bell was elected an Associate Member of the American Society of Civil Engineers on April 7, 1915, and a Member on October 10, 1927.

JOHN GEORGE BLOOM, M. Am. Soc. C. E.[1]

DIED MARCH 28, 1940

John George Bloom was born on November 25, 1867, at Xenia, Ohio. He was graduated from the Ohio State University, at Columbus, Ohio, with the degree of Civil Engineer in June, 1889.

His first engineering work began in July, 1889, as assistant engineer with the Pennsylvania Railroad Company. From October, 1889, to March, 1890, he served as draftsman with the city engineer of Bucyrus, Ohio, making maps of cities in Ohio and the Indiana gas fields. The next two months he spent with the Hocking Coal and Iron Company at Buchtel, Ohio, as draftsman and instrumentman. Until October, 1890, he was assistant engineer with the Kenova Land Association laying out town sites, grading streets, and making contour maps of Kenova, W. Va.

The following year Mr. Bloom joined the Norfolk and Western Railway Company as assistant supervisor and assistant to the division engineer, Eastern Division, Crewe, Va. Then he returned to his home town as assistant city engineer, and in April, 1892, he entered the service of the Baltimore and Ohio Southwestern Railroad Company at Cincinnati, Ohio, as draftsman. In November, 1893, he was promoted to assistant engineer, in charge of office and field work, and two years later he was promoted to division engineer, Springfield Division, in Flora, Ill., in charge of maintenance of way and structures. In June, 1896, Mr. Bloom was appointed principal assistant engineer of the entire system, in charge of office and field work, design, revision of grades, and new construction; and in February, 1900, he was division engineer of the Ohio Division, at Chillicothe, Ohio, in charge of maintenance of way and structures. He remained in this position until April, 1892, when he became division engineer, Newcastle Division, of the Baltimore and Ohio Railroad Company, in charge of maintenance of way and structures.

Mr. Bloom entered the service of the Chicago, Rock Island and Pacific Railway Company in June, 1903, as principal assistant engineer of the Southwestern District, at Chicago, Ill., and Topeka, Kans., in charge of maintenance and construction. In July, 1905, he was appointed engineer in charge of maintenance and construction of the Southwestern and Choctaw districts and the St. Louis, Colorado and Kansas City Railroad, a subsidiary at Topeka. From January, 1909, to August, 1912, he served as president of the Southern Ballast Company, at Mill Creek, Okla.

---

[1] Memoir prepared by L. C. Fritch, M. Am. Soc. C. E.

A record of his various positions follows:

August, 1912, to December, 1913—superintendent of construction of the John F. Stevens Construction Company on Salmon River Dam and Power House, at Altmar, N. Y.

December, 1913, to October, 1914—with Grace Construction Company on double track work on Illinois Central Railroad at Dyersburg, Tenn.

October, 1914, to June, 1916—valuation work for the Chicago, Rock Island and Pacific Railway Company.

June, 1916, to August, 1918—superintendent of the Chicago, Rock Island and Pacific Railway Company on the Amarillo Division, at Amarillo, Tex.

August, 1918, to May, 1921—superintendent of the Louisiana Division of the same company, at El Dorado, Ark.

May, 1921, to May, 1922—division engineer, Nebraska Division, at Fairbury, Nebr.

May, 1922, to February, 1929—engineer, Maintenance of Way Department, of the entire system of the Chicago, Rock Island and Pacific Railway Company at Chicago.

Resigning voluntarily on February 1, 1929, Mr. Bloom retired from railroad service and moved to Pasadena, Calif.

The writer's acquaintance and friendship extended over almost the entire period of service enumerated previously. The most outstanding characteristic of John George Bloom was his thoroughness, accuracy in his work, and dependability. He was modest and unassuming, but most kind and affable, and endeared himself to all who came in contact with him.

During the forty years of active railroad service he rendered valuable and pioneering service on some of the most prominent railroads of the country. From his large experience in railroad engineering he contributed much to the art of the rehabilitation of the railroads in the revision of line and grades, and did most valuable work in this industry when it was in its infancy.

He spent his retirement years in Pasadena, where he built a fine home and enjoyed his well-earned leisure with his beloved wife. He left no children, and his nearest relative is a niece, Edna Bloom. He lies at rest beside his wife in the beautiful Forest Lawn Memorial Cemetery at Los Angeles, Calif.

Mr. Bloom was a Scottish Rite Mason.

Mr. Bloom was elected a Member of the American Society of Civil Engineers on July 9, 1906.

NORMAN FREED BROWN, M. Am. Soc. C. E.[1]

DIED APRIL 11, 1937

Norman Freed Brown was born at Coudersport, Pa., on March 20, 1878, the son of Thomas Benton and Mary (Housekeeper) Brown.

---

[1] Memoir prepared by a Committee of the Pittsburgh Section composed of Vernon R. Covell, M. Am. Soc. C. E., Chairman, and the late Samuel Eckels and the late Charles M. Reppert, Members, Am. Soc. C. E.

His technical training was obtained at the University of Pennsylvania, at West Philadelphia, Pa., and the Carnegie Institute of Technology, at Pittsburgh, Pa., where he took special work.

He began his engineering career with the Pennsylvania Railroad Company on January 3, 1898, as a rodman and was promoted through the various grades to the position of assistant engineer of construction. As such he was engaged in railroad construction in western Pennsylvania, especially in Pittsburgh and vicinity. Among the projects of which he was in charge were the Brilliant Branch or "Cut-Off"; erection of the Port Perry Bridge over the Monongahela River; construction of the Duquesne (Pa.) Elevated Railroad along the Allegheny River, including warehouses and delivery yard; East Liberty, Pa., and Swissvale, Pa., passenger stations, each requiring change of street grades; and the Pitcairn, Pa., east-bound classification yard.

Mr. Brown was granted a leave of absence on January 31, 1918, and was commissioned in the rank of Major in the Reserve Corps of Engineers, January 24, 1918. He served in France with the American Expeditionary Forces from February, 1918, to April, 1919, attached to the staff of the late Brig. Gen. W. W. Atterbury,[2] M. Am. Soc. C. E., who was Director General of the American Army Transportation Corps. While serving with General Atterbury, Major Brown assisted in the planning and developing of numerous transportation installations and facilities, particularly on the railroads utilized as the first line of communication. He made an extensive study of the French railroad system with regard to traffic density and capacities for the development of the second line of communication and the future development of the third and fourth lines of communication to be used by the United States Army as planned for the peak of combatant troops in action for the planned spring drive of 1919. This study terminated with the signing of the Armistice; however, a complete arrangement had been entered into with the French military services and many plans had been developed for the required facilities for American train operations. Following the signing of the Armistice, Major Brown was assigned to the Inter-Allied Railways Commission, formed under Article 7 of the terms of the Armistice, and by this commission he was delegated as the American representative of the Commission for the reception of German railway equipment with headquarters at Metz, France, and receiving stations at Coblenz and Cologne, in Germany, where the railway equipment was delivered, inspected, accepted, and shipped to France, in accordance with the terms of the Armistice agreement. He was honorably discharged from the U. S. Army on March 1, 1919, and he returned to the service of the Pennsylvania Railroad Company on April 1, 1919, as assistant engineer.

On March 1, 1920, Major Brown was appointed assistant to the chief engineer. During this period he was engaged in adjusting settlements between the federal government and the railroad corporation.

On April 1, 1921, he was again granted a leave of absence and was appointed director of the Department of Public Works of Pittsburgh. During this period the following work was planned, contracts let, and construction completed or started: Beechwood Boulevard Bridge; Center Avenue Bridge over the Pennsylvania Railroad; Island Avenue Bridge over the tracks of the Pittsburgh, Fort Wayne and Chicago Railway; and Boulevard of Allies along the Monongahela River, leading from downtown Pittsburgh to the Oakland district, requiring heavy hillside construction and steel viaduct work.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1518.

On January 1, 1922, he resigned as director and was elected vice-president of the Dravo Corporation, where he had charge of the development and securing of new business in heavy bridge and river work. On May 31, 1923, he organized the company of Brown and Reppert, consulting engineers.

Major Brown was chosen by the county commissioners as director of the newly formed Department of Public Works of Allegheny County on January 1, 1924. He organized this department by combining existing construction units and forming new ones. During the eight years that he held the position, he had charge of the most extensive construction program in the history of Allegheny County, which included 98 highway bridges, twelve of which were large river bridges, and ten of which crossed wide and deep ravines, including the George Westinghouse Memorial Bridge, which has the longest span, reinforced-concrete arch in the Americas; the Allegheny River and Ohio River boulevards, each leading from Pittsburgh to suburban sections; construction or reconstruction of more than 300 miles of county roads; Armstrong highway tunnel; the County Airport; and County Office Building. During this period he had developed and patented a reinforced-concrete railroad tie. On November 15, 1931, he resigned as director in order to devote his time to the further development and promotion of the concrete tie, which has been tested in actual service in a number of localities.

Major Brown was a great organizer and had the faculty of inspiring intense activity and loyalty on the part of those whom he directed.

On April 4, 1906, he was married to Hattie Hoobler who survives him. Also surviving are two daughters, Mary (Mrs. Sydney W. Binns) and Nancy Bell (Mrs. Thomas E. Diehl).

Major Brown was elected an Associate Member of the American Society of Civil Engineers on June 5, 1907, and a Member on November 30, 1909.

EVERETT N. BRYAN, M. Am. Soc. C. E.[1]

DIED DECEMBER 17, 1939

Everett N. Bryan was born in Montezuma, Poweshiek County, Iowa, on April 9, 1884, the son of Neri E. and Mary Elizabeth (Job) Bryan.

He went to California with his parents in 1887, received his education in the public schools of that state, and was graduated in 1907 from the University of California, at Berkeley, Calif., with the degree of Bachelor of Letters.

---

[1] Memoir prepared by a Committee of the Sacramento Section consisting of Edward Hyatt, M. Am. Soc. C. E., as Chairman, and Mark S. Edson and Walter E. Stoddard, Assoc. Members, Am. Soc. C. E.

For two years after his graduation he was employed by the Western Pacific Railroad Company on railroad location in Nevada. He entered the employ of H. D. Hanford, consulting engineer of Seattle, Wash., in 1909, and for a year was engaged in engineering work that involved irrigation and hydroelectric power developments in eastern Washington. In 1910 Mr. Bryan returned to California and until 1921 was actively engaged with irrigation construction and operation. During four years of this period he was chief engineer of the Waterford Irrigation District.

Following a period of nearly a year of private practice in San Francisco, Calif., he accepted a position with the State Water Commission, State of California, on July 1, 1921. The Water Commission Act had been put into effect some years before, but because of the shortage of engineers during the World War period, the work of the Commission had not been standardized. Mr. Bryan immediately took a leading part in perfecting the procedure subsequently put into effect, supervising the initiation and perfection of water rights in accordance with the Water Commission Act. As a result of his wide experience in irrigation and hydroelectric engineering practice, and his activity in the Division of Water Resources, which succeeded to the duties of the State Water Commission, he became one of the most eminent engineering authorities on water rights in California. At the time of his death he was the supervising hydraulic engineer of the Division of Water Resources.

As engineering was his profession, so also was it his avocation. He was keenly interested in everything affecting his work and ever strived to uphold the high standards of the profession. Among many papers which he contributed to leading engineering periodicals on various phases of engineering, perhaps the one which received the highest recognition was that on "Hydro-Electric Power as a By-Product of Agricultural Storage,"[2] published in 1925.

Civic affairs always commanded his attention. In 1928 he was appointed a member of the Sacramento Water Commission for the investigation of a water supply for the City of Sacramento, Calif. He also served on other civic committees, giving freely of his time and counsel.

When the law for the registration of civil engineers was first proposed, Mr. Bryan took a leading part in drafting the proposed act and, as a mark of respect, received Certificate of Registration No. 4 under the act, the members of the first Board of Registration having been assigned the first three numbers.

Mr. Bryan was active in the formation of the Sacramento Section of the Society, was a charter member of this organization, was its fifth president, and served on many of its committees. He labored earnestly and effectively for the best interests of the Section and was one of its acknowledged leaders.

While he was President of the Section, Mr. Bryan, and the committee appointed by him, was instrumental in naming the reservoir on the Merced River, formed by the Merced-Exchequer Dam of the Merced Irrigation District, Lake McClure in honor and in memory of the late Wilbur F. McClure,[3] M. Am. Soc. C. E., state engineer of California from 1912 to 1925.

---

[2] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 910.

[3] For memoir, *loc. cit.*, Vol. 91 (1927), p. 1106.

During Mr. Bryan's term as President of the Section, a movement was also initiated for the erection of a monument on the park fronting the Southern Pacific Railroad station, at Sacramento, to the memory of the late Theodore D. Judah,[4] M. Am. Soc. C. E., first chief engineer of the Central Pacific Railway Company. The monument was later constructed by the employees of the Southern Pacific Railroad Company. If it had not been for the activity of Mr. Bryan and his committee, it is doubtful whether the monument would be standing today.

In later years, Mr. Bryan took an active interest in the topographic mapping program sponsored by the Section and in the activities of the Section's committee on engineering salaries. He served continuously as chairman of the latter committee from 1936 until his death.

Mr. Bryan was a member of Sacramento Lodge No. 40, Free and Accepted Masons of the State of California, and a member of the Sutter Club of Sacramento.

He had a gift of personal charm and affability, was a conscientious worker, loyal to principle, a faithful public servant, and a loyal friend.

He was married in Berkeley, on March 25, 1911, to Gladyes Huber Trumbo of Berkeley. He is survived by his widow and his son, Everett Elgin Bryan. A sister, Myrtle, and five brothers, Ross, Claude, Ellis, Jasper, and Homer Bryan, also survive.

Mr. Bryan was elected an Associate Member of the American Society of Civil Engineers on November 3, 1915, and a Member on July 7, 1925.

WALTER CARL BUETOW, M. Am. Soc. C. E.[1]

Died April 23, 1939

The sudden death of Walter Carl Buetow was a real loss to his many friends and acquaintances. He was a man of outstanding personality and character, true in his friendships, and one who always endeavored to see the good in all persons. For these characteristics he was loved and greatly respected, not only in social life, but also in business life. He possessed a dignified bearing, which always left its impression on new acquaintances at first meeting.

Mr. Buetow was born on August 11, 1884, at Milwaukee, Wis., the son of Charles J. L. and Ida (Bierbauer) Buetow.

His life was entirely devoted to his selected field of civil engineering after graduation from the University of Wisconsin, at Madison, Wis., in 1908. First he served as a design and construction engineer with various firms for approximately three years. Then, when the State of Wisconsin organized a Highway Department, he entered its employ as bridge designer. Service with the state covered nearly sixteen years in various capacities, and included the position of chief engineer for three years. He served with the Stein Construction Company, bridge builders, for four years as chief engineer, during which period he constructed one of the largest and longest "causeway" structures in Florida.

---

[4] For memoir, see *Transactions*, Am. Soc. C. E., Vol. XXXVIII, December, 1897, p. 448.

[1] Memoir prepared by Gordon F. Daggett, M. Am. Soc. C. E.

His hobby was his profession—namely, bridge design—and the highways of Wisconsin have many lasting examples of his work and beautiful layouts which combined art with scientific design.

At the time of his death he was in the employ of the City of Milwaukee, for which city he designed the Cherry Street Bridge, and was in charge of construction work.

Mr. Buetow was married to Marie Endron, of Evansville, Ind., who survives him, together with his mother, and a sister, Wonda Buetow.

One of his intimate friends recently described his death as having taken "a real man and wonderful engineer from our midst."

Mr. Buetow was elected a Member of the American Society of Civil Engineers on August 18, 1930.

RALPH HOWE CADY, M. Am. Soc. C. E.[1]

DIED NOVEMBER 29, 1939

Ralph Howe Cady, the son of George Alonzo Cady and Clara (Cline) Cady, was born in Sault Ste. Marie, Mich., on August 22, 1893. The Cady family ancestors came to Massachusetts from England early in the seventeenth century and a branch of the family later migrated to Michigan. Mr. Cady was educated in the public schools in Sault Ste. Marie and studied at the University of Michigan, at Ann Arbor, Mich., in the class of 1916. In 1918 he received the degree of Bachelor of Science in Civil Engineering from the University of Michigan. He was a member of Sigma Xi and Tau Beta Pi fraternities.

During 1916–1917 Mr. Cady acted as engineering assistant for the Michigan Northern Power Company of Sault Ste. Marie, inspecting pneumatic caisson foundations, investigating compensation works and problems in connection with the control of Lake Superior water levels, canal gaging, and other work. From July, 1918, to January, 1919, he was with the U. S. Army Engineering Section Sanitary Corps, as Sergeant, First Class, on waste disposal experimentation, and later as Second Lieutenant in charge of water supply at Payne Field, West Point, Miss. He was honorably discharged in 1919.

He was associated with Hoad, Decker and Drury, Consulting Engineers of Ann Arbor, from February, 1919, to July, 1920, first as assistant engineer on field work and design of water supply and sewage plants for Highland

---

[1] Memoir prepared by E. S. Skillin, Assoc. M. Am. Soc. C. E.

Park, Owosso, Muskegon, Muskegon Heights, Ann Arbor, and Plymouth, Mich.; and then as designing engineer, which position he held for six months.

Mr. Cady joined the organization of the Frederick Snare Corporation, Engineers and Contractors, New York, in July, 1920. After a few months in the main office he was sent to the office in Havana, Cuba. Until 1924 he was assistant engineer on design and construction, and from then until 1927, he acted as engineer and assistant manager of the Havana office. During that period a number of important projects were developed and constructed, notably the complete steamship terminal for the Ward Line Steamship Company, consisting of a large concrete pier, concrete and steel warehouses, wharves, and bulkheads—costing more than $3,000,000. While in Cuba he had charge of, or assisted with the engineering work on, many other projects in various parts of the island which required investigation, reports, designs, estimates, and the actual construction, of bridges, water supply, power houses, sugar mills, and industrial buildings.

Following his transfer to the main office of this company Mr. Cady made a complete technical, commercial, and financial report with preliminary plans and estimates for a proposed ocean and river terminal for the City of Barranquilla, Colombia, S. A., approximating $5,000,000. He made a similar report on the port of Callao, Peru, for the Peruvian Government, consisting of a steamship terminal with piers, wharves, warehouses, custom house, and railway connection, and the problems involved in the construction of a sheltered harbor by building rock breakwaters, dredging, etc., costing in all more than $8,000,000. After the award of this contract, based on his design, he assisted in supervising the construction work; and later the dock facilities at Callao were enlarged to provide for the increased tonnage that was attracted to the port because of the success of the first terminal. This additional work was also done from designs prepared by Mr. Cady and involved the expenditure of $1,500,000.

From 1928 Mr. Cady traveled extensively throughout South America as foreign representative of the Frederick Snare Corporation making studies, surveys, designs, estimates, and reports for various port works such as Asunción, Paraguay; Arica, Chile; and Turiamo, Venezuela. He designed the ocean and river boat terminal at Cartagena, Colombia, completed at a cost of approximately $3,000,000, and supervised the construction through completion. The new port of Matarani, Peru, for the Peruvian Government, estimated to cost about $4,000,000, was designed by Mr. Cady. This work involved all the problems for developing a port at a location where no harbor of any nature had previously existed and included breakwaters in deep water, bulkheads, warehouses, water supply, electric power plant, and other facilities.

In addition to the foregoing, Mr. Cady was associated with studies, plans, and estimates for port work at Tocopilla, Chile, and water works for Cartagena. While in the New York office he was engaged in the construction problems involved in the building of the large Tygart River concrete dam at Grafton, W. Va., for the U. S. Engineers, a dam costing $8,000,000. The most recent project developed by Mr. Cady was the important terminal for oil shipment near Guanta, Venezuela, completed in 1940 from plans prepared by him. His work was of a highly diversified character and included the studies and designs of many important structures requiring not only the best engineering practice but the consideration of local requirements, consultation, and negotiations with government and municipal authorities, particularly in Latin America. His knowledge of Spanish, familiarity with native customs and social life, his pleasing personality, and wide experience made him unusually well equipped for foreign activities. He was highly respected by all with whom he came in contact, as a thoroughly competent engineer and as a man of the highest integrity.

From time to time Mr. Cady prepared papers on engineering subjects which were published in technical journals, such as the *Proceedings* of the Society, the *Engineering News-Record, Port Works,* and the *Marine News.*

Mr. Cady was interested in outdoor life. He was a keen fisherman and fond of the woods. While in Havana he was a member of the Country Club of Havana, and of the Knickerbocker Country Club of Englewood, N. J. His travels covered practically all of the countries of South America and the West Indies, by ships, planes, and automobiles, so that he was familiar with the principal cities on the coast and in the interior, and in some cases isolated locations far from the main centers.

In 1926, Mr. Cady was married to Carolyn Paxton of Hammond, Ind., and he is survived by his widow, and a son, Paxton; three brothers, Mark S. Cady, G. Fitch Cady, and S. Cline Cady; and a sister, Mrs. Edith Cady Gilhooley.

Mr. Cady was elected an Associate Member of the American Society of Civil Engineers on July 9, 1923, and a Member on July 6, 1936.

THOMAS JENKS CARLILE, M. Am. Soc. C. E.[1]

DIED NOVEMBER 28, 1939

Thomas Jenks Carlile was born on August 20, 1872, at Chattanooga, Tenn., the son of William Rich and Margaret (Wylde) Carlile. He was educated in the public schools of Chattanooga.

He began his engineering career in June, 1888, when he entered railroad service at Poughkeepsie, N. Y., as chainman on the location of the Hudson Connecting Railroad. He served as rodman, transitman, and assistant engineer on the location and construction of the Pennsylvania, Poughkeepsie and Boston Railroad. He went from the Poughkeepsie Bridge Route to the Dutchess County Railroad Company where from March to August, 1890, he was assistant engineer on location.

In August, 1890, he joined the engineer corps of the Norfolk and Western Railway Company as assistant engineer in charge of ten miles of construction in West Virginia on the Ohio Extension, where he remained until February,

---

[1] Memoir prepared by John M. Belknap, M. Am. Soc. C. E.

1891. He was engaged as instrumentman on the location of the Adirondack and St. Lawrence Railroad from April to October, 1891, and went from this work to spend eight months as levelman for the New York and New England Railroad Company. His next assignment was as assistant engineer for T. E. Crimmins on the construction of the Third Avenue Cable Road in New York, N. Y., where he was employed from June to November, 1892.

From November, 1892, to March, 1893, he worked as assistant engineer for the late E. P. Roberts,[2] M. Am. Soc. C. E., on surveys for the location of a highway from West Point, N. Y., around Storm King Mountain to Cornwall, N. Y. In May, 1893, he was appointed to the position of rodman in the Bureau of Surveys in Philadelphia, Pa. Later he became assistant engineer in charge of the field corps on general city survey work and on the construction of the Pennsylvania Avenue Subway and Tunnel for the Philadelphia and Reading Railroad Company and on dredging in the Delaware and Schuylkill rivers.

He resigned from the Bureau of Surveys in June, 1900, to accept the position of principal assistant engineer for the Philadelphia Crude Ore Company on surveys in the Aleutian Islands, Alaska, and remained on this work until October, 1900. He returned to the Bureau of Surveys, in Philadelphia, in December, 1900, and served as assistant engineer on the location of Torresdale Boulevard until May, 1901, when he resigned to become assistant engineer on the location of the Cornwall and Western Railroad. This work was completed in July, 1901, and two months later he returned to the Bureau of Surveys (Filtration Department), in Philadelphia, on the location surveys and as assistant engineer on dredging in the Delaware and Schuylkill rivers.

He remained with the Bureau of Surveys until January, 1903, and from that time until January, 1904, he was engineer in charge of location and construction for the Beaver Creek Railroad Company in West Virginia. He went to San Juan, Puerto Rico, in April, 1904, as locating engineer for the West Indies Construction Company on the surveys for the proposed railroad of the Porto Rico Railway, Light and Power Company across the island from San Juan to Ponce.

Returning to the United States in April, 1905, he accepted a position as locating engineer with the New Jersey Short Line Railroad Company. He completed this work in June, 1905, and in July, 1905, he went to Kansas City, Mo., as assistant chief engineer on the location and construction of the Missouri and Kansas Interurban Railroad from Kansas City to Olathe, Kans. He resigned this position in November, 1905, to become assistant engineer with the Long Island Railroad Company at Jamaica, N. Y.

In April, 1907, he was appointed principal assistant engineer and from that time until his retirement, due to ill health, in April, 1938, he was in charge of all field engineering and in general charge of all construction work, with the exception of the Bay Ridge and Jamaica Improvements.

During his term as principal assistant engineer of the Long Island Railroad Company many important improvements were completed including several major grade crossing eliminations.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXII, June, 1911, p. 593.

Mr. Carlile was a lifelong member of the Protestant Episcopal Church and was one of its most valued and prominent laymen. From 1917 until his death, he was vestryman and warden of St. George's Episcopal Church of Hempstead, N. Y. He was also a member of the executive board of the diocese and held other offices in his church.

The foregoing sketch covers fifty-one years of active work in engineering, largely devoted to railroad location and construction. The writer's friendship and association with Mr. Carlile extended over a period of more than thirty-four years and began when they met in San Juan, Puerto Rico, in April, 1904. This association was continued in July, 1905, on the location and construction of the Missouri and Kansas Interurban Railroad at Kansas City, and was further continued on the Long Island Railroad from January, 1911, to September, 1914. Although their paths in business separated, the friendship continued firm and strong, and the memory of that friendship is one of the finest of a lifetime. He was a true and loyal friend.

He was a very capable construction engineer and a man of splendid executive ability. He possessed a pleasing personality and was a delightful companion. He was married on June 16, 1908, to Alice Phelps Stokes of Philadelphia, who survives him. Also surviving is one son, Thomas Stokes Carlile, born at Flushing, Long Island, N. Y., on July 4, 1909.

Mr. Carlile was a member of the American Railway Engineering Association and the American Association of Engineers.

Mr. Carlile was elected a Junior of the American Society of Civil Engineers on March 3, 1896; an Associate Member on March 6, 1901; and a Member on December 3, 1907.

ALLAN WINTER CUDDEBACK, M. Am. Soc. C. E.[1]

Died December 4, 1938

Allan Winter Cuddeback was born in Cuddebackville, N. Y., in 1868. The family were French in origin, and in this country were farmers in the town which is named for them. One sister survives and the family still owns the farm in Cuddebackville.

Mr. Cuddeback was enrolled with the Freshman Class at Cornell University, at Ithaca, N. Y., in the fall of 1890, and completed the work of one year. Then seeking, as he said, the broadening of view which would come from education in a distant section of the country he entered Stanford University, at Stanford University, Calif., which first opened its doors in the fall of 1891. As a transfer student he completed his course in 1894 and thus became one of Stanford's first engineering graduates under the guidance of Charles D. Marx, Past-President and Hon. M. Am. Soc. C. E., who then directed the engineering course.

---

[1] Memoir prepared by Thomas H. Wiggin, Thaddeus Merriman, and John H. Cook, Members, Am. Soc. C. E. Mr. Merriman died September 26, 1939.

In the summer of 1891 he was leveler for the East Jersey Water Company, one of the group of private companies in New Jersey with which he was later to become closely identified through many years. Between the time of his graduation in 1894 and October, 1898, when he finally became identified with that group of water companies in New Jersey, he had a variety of worthwhile jobs which contributed to the breadth of his engineering experience. These jobs included surveys, plans and specifications for a system of sewers at Palo Alto, Calif. (May to July, 1894); charge of a U. S. Coast and Geodetic Survey party engaged in fixing the boundary line between the states of California and Nevada (July, 1894, to January, 1895); assistant engineer in charge of surveys and construction of irrigation ditch for the Stanislaus and San Joaquin Land and Water Company, California (January to June, 1895); topographer in charge of magnetic observations and reconnaissance on surveys of boundary between the states of California and Nevada (June, 1895, to January, 1896); with East Jersey Water Company on construction of Newark, N. J., conduit No. 2 (January to November, 1896); survey for Passaic Valley, N. J., sewerage system, then topographical surveys of two New York, N. Y., parks (November, 1896, to February, 1897); surveys and construction for Metropolitan Street Railway Company, New York City (March, 1897, to March, 1898).

In March, 1898, Mr. Cuddeback made the connection with the group of water companies in Metropolitan New Jersey which was to endure actively from that time until 1926, and thereafter in a less active way until his death. These companies included the Passaic Water Company, the East Jersey Water Company, Jersey City Water Supply Company, Acquackanonk Water Company, and Montclair Water Company. The territory supplied included Paterson, Passaic, Clifton, Montclair, and Bayonne.

Most of these companies were affiliated with the famous S. U. M. (Society for Establishing Useful Manufactures), founded by Alexander Hamilton, which society is still owner of the water power at the Great Falls on the Passaic River in Paterson, N. J. Of these companies the late Clemens Herschel,[2] Past-President and Hon. M. Am. Soc. C. E., inventor of the venturi meter, was for many years chief engineer and manager, followed by the late J. Waldo Smith,[3] Hon. M. Am. Soc. C. E. The latter engaged Mr. Cuddeback and through the following years gave him the opportunity for training and experience which made him the skilled and rounded water works constructor and operator who was so well known in his field. Mr. Cuddeback often quoted the words with which Mr. Smith introduced him to his work, telling him he was conferring on him no title but for him to go in and make a place for himself. This he did, becoming successively assistant superintendent, superintendent and engineer, and finally, after Mr. Smith was called to take charge of water works construction for New York City, becoming superintendent and vice-president of the combined companies which later were formed into the Passaic Consolidated Water Company. An intimate friendship existed between Mr. Cuddeback and Mr. Smith until ended by the latter's death in 1933.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1419.

[3] For memoir, *loc cit.*, Vol. 101 (1936), p. 1502.

Among the works which were executed during Mr. Cuddeback's connection with these large New Jersey companies were the Boonton Dam, aqueduct, and the first 72-in. steel pipe line from Boonton to Jersey City, many steel pipe lines which were among the early ones in the country, and the Little Falls rapid sand filter plant of 32 mgd capacity, first of the large masonry plants of this type, for which the late George W. Fuller,[4] M. Am. Soc. C. E., was consulting sanitary engineer and the late William B. Fuller,[5] M. Am. Soc. C. E., was consulting structural and resident engineer.

Mr. Cuddeback made the accuracy and maintenance of water meters a special study, and due in great measure to the skill and energy which he applied to the task of metering all services, gradually and completely, the supply from the Passaic River continued to be adequate for the cities of Paterson, Passaic, Clifton, Bayonne, Montclair, and other communities until the condemnation in 1930 of the works of the Passaic Consolidated Company by certain of the cities supplied. With a rapidly rising population and industrial demand, the consumption actually fell greatly during the several-year period of metering. Mr. Cuddeback's methods of meter testing and repairing are still living and spreading through the younger men whom he trained.

During his many years with the New Jersey companies, Mr. Cuddeback did considerable work as a consulting water works engineer for other plants, and managed some outside companies including that at Massillon, Ohio.

In 1926 Mr. Cuddeback became vice-president and general manager of the Federal Water Service Corporation, a holding company formed at that time, and aided in the appraisal, purchase, and organization into state companies of more than 100 water companies in the states of New York, New Jersey, Pennsylvania, Ohio, Illinois, West Virginia, Alabama, California, Washington, and Oregon. The total value of these companies was more than $100,000,000 and the population supplied was about 2.5 million. Many of the companies were "run down" and the work of rehabilitating them was done under Mr. Cuddeback's general direction. In the four years previous to 1931, the work involved an expenditure of about $7,000,000 each year in extensions, repairs, and new works, and lesser but substantial sums in the following years of depression. A few years before his death he retired from the general managership of Federal Water Service Corporation but remained a director and president of the New York and New Jersey water service companies until a few months before his death, which was much hastened by an attack of pneumonia in the previous year. He died on Sunday, December 4, 1938.

Mr. Cuddeback was a member of the American Water Works Association and New England Water Works Association. He served as president of American Water Works Association from June, 1926, to June, 1927. He was a member of the Hamilton Club of Paterson, N. J., North Jersey Country Club, and Stanford Club.

Mr. Cuddeback had a gift for friendship, and his loyalty and broad human understanding and sympathy endeared him to all his associates. He was fond of watching the by-play of human actions and motives; he understood the strength and was tolerant of the weaknesses of his fellow men and women. At the same time he was firm and direct when action was required. Like many another good engineer, he was very fond of a game of poker with his friends and was a skilful player. It never troubled him if he lost; when he lost it was just a part of the expense of living; when he won he managed to spend his winnings promptly for the benefit of others.

---

[4] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1653.

[5] For memoir, *loc. cit.*, Vol. 87 (1924), p. 1337.

Surviving are his second wife, the former Edith A. Finley; two children of his first marriage, Louise B. and Thomas M. Cuddeback; and a sister, Mrs. F. Ketchum.

Mr. Cuddeback was elected an Associate Member of the American Society of Civil Engineers on April 5, 1899, and a Member on March 1, 1910.

JAMES EUGENE CURTIS, M. Am. Soc. C. E.[1]

DIED AUGUST 4, 1939

James Eugene Curtis was born in Washington, D. C., on October 11, 1883, the son of James M. and Florence A. (Turton) Curtis. His early education was obtained at the Emerson Institute of Washington, and he later attended George Washington University, in Washington.

The first engineering position held by Mr. Curtis was that of draftsman and surveyor with the Pressey and Weller Company of Washington on water works and building construction. In this position he acted as an assistant on design of water distribution systems for various southern cities and was employed on topographical surveying and building location.

In 1905 he entered the employ of the War Department in the Washington Aqueduct section of the U. S. Engineer Office, which has jurisdiction over the collection, purification, pumping, and transmission of water for the City of Washington. This was an important step in Mr. Curtis' life, as he remained with this office continuously until his death, a period of thirty-four years. During this time he was promoted successively from surveyman to senior engineer.

When Mr. Curtis entered the employ of the Washington Aqueduct the city was in the process of completing the construction of the large slow-sand filtration plant at the McMillan Reservation. Mr. Curtis worked directly under E. D. Hardy, the engineer in charge of the work, and was entrusted with the completion of the designs of many of the superstructures. He also participated in the design of a 10-in. suction dredge and the design and construction of an hydraulic sand-washer system for McMillan Reservation, which doubled the efficiency of operation.

In 1910 he was appointed junior engineer and worked on the design and construction for the Washington Aqueduct tunnels, installation of water meters of government services, and the construction of various improvements to McMillan Reservation grounds, including roads, walks, and courts.

---

[1] Memoir prepared by E. A. Schmitt, Esq., and P. O. Macqueen, M. Am. Soc. C. E.

In 1912 Mr. Curtis was appointed assistant superintendent of the Washington Aqueduct under Mr. Hardy, and in this position he had charge of a great many important improvements to the water supply system, including a cast-iron lining for Cabin John Aqueduct Bridge, the design and construction of the remodeling of Georgetown Reservoir, and the investigation of the Patuxent River as a source of water supply for the city.

In 1921 Mr. Curtis was appointed superintendent of operations for the Washington Aqueduct and in 1923 field superintendent supervising the construction of the increase of water supply work. This project included conduits, tunnels, covered reservoirs, pumping stations, transmission water lines, a new rapid sand filtration plant, a hydroelectric generating station, and various minor structures. The total cost of this construction work was approximately $9,000,000. In 1928 Mr. Curtis was appointed civil engineer, and in 1929 senior engineer. He continued in charge of the operations of the Washington Aqueduct and held this position at the time of his death on August 4, 1939.

Mr. Curtis was a man of quiet manners and sound judgment with a high degree of self-confidence. During the entire thirty-four years of his experience in connection with the Washington Aqueduct he had an excellent insight into water-works practices, and his knowledge of all the details of the various structures of the Washington Aqueduct system was of great value to the U. S. Engineer Office.

Mr. Curtis was married to Lillian Gayle on July 21, 1909. There were no children.

He was a member of the Blue Lodge, Consistory and Shrine Masonic Fraternity, and also held memberships in the American Water Works Association, the American Society of Military Engineers, and the Washington Society of Engineers.

Mr. Curtis was elected an Associate Member of the American Society of Civil Engineers on April 30, 1912, and a Member on April 12, 1926.

WALTER WHALEY CURTIS, M. Am. Soc. C. E.[1]

Died June 29, 1940

Walter Whaley Curtis, the son of John Decker and Sarah Catherine (Marston) Curtis, was born in Whaleysville, Md., on September 28, 1863. His early education was acquired in the public schools of Wilmington, Del.

In 1881 Mr. Curtis was employed by the Atchison, Topeka and Santa Fe Railway Company at Las Vegas, N. Mex. Later in the same year he was employed by the late Charles Frederick Loweth,[2] Past-President, Am. Soc. C. E., in the construction of two narrow gage railroads near Des Moines, Iowa.

---

[1] Memoir prepared by Frank O. Ray, Assoc. M. Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1488.

Upon the termination of this work he returned to the Atchison, Topeka and Santa Fe Railway Company at Topeka, Kans., under the division engineer on work which involved the location and construction of some branch lines and various structures.

In the fall of 1883 he was again employed by Mr. Loweth at St. Paul, Minn., and assisted in the design of bridges. He became greatly interested in this work but found that he did not have sufficient technical education, so he entered the Thayer School of Engineering at Dartmouth College, in Hanover, N. H., and received the degree of Civil Engineer in 1886.

After graduation he joined Mr. Loweth at St. Paul and remained with him until 1887 when he became resident engineer on the construction of the Atchison, Topeka and Santa Fe Railway bridge over the Mississippi River at Ft. Madison, Iowa.

In 1888 he returned to St. Paul where he continued the practice of engineering, designing, and supervising the construction of bridges, water works, and various engineering structures. Among these was one of the first elevated water tanks which has ever been constructed on a steel tower.

In 1891 he moved to Chicago, Ill., to represent the Pittsburg Bridge Company; and among many other structures he erected the Halsted Street Lift Bridge, which was the first high lift bridge ever built.

Severing his connection with the Pittsburg Bridge Company in 1896, he established an engineering and contracting business which he continued until 1913. During this time he investigated the results of railroad tie treatments and assisted in the extension of this industry.

Mr. Curtis made investments in coal lands in Colorado, and in 1913 he found it necessary to devote his entire time to these interests. In 1929 failing health forced his retirement.

He was a student and great reader of engineering literature, and kept up his interest in his profession long after he retired from active practice.

In 1887 he was married to Sarah Marston at Fairlee, Vt. Two sons, Robert C. Curtis and Steven G. Curtis, survive him.

Mr. Curtis was formerly a member of the Western Society of Engineers and of the American Railway Engineering Association.

Mr. Curtis was elected a Member of the American Society of Civil Engineers on September 5, 1888, and served as President of the Colorado Section in 1928–1929.

WILLIAM CHANNING CUSHING, M. Am. Soc. C. E.[1]

DIED JANUARY 11, 1940

William Channing Cushing was born in St. John, New Brunswick, Canada, on March 18, 1863 (of United States citizenship), the second son of

---

[1] Memoir prepared by Allston T. Cushing, M. Am. Soc. C. E.

George Byron and Annie Tilton (Scammell) Cushing. His father was one of the pioneer lumber manufacturers and merchants of St. John, having moved there from Winterport, Me., in 1853. In 1857 he joined his uncle, André Cushing, in the firm André Cushing and Company, in which firm he was a partner until his death in 1888.

William Cushing was educated in the schools of St. John and entered the University of New Brunswick at Fredericton, New Brunswick, in 1881, being graduated with the degree of Bachelor of Arts in 1884 with honors in the Classics, English, and French. He won the English Scholarship of 1883, and half of the French Prize of 1884, there being a tie with his competitor. His examinations entitled him to collegiate "Honors in Classics" in 1881–1882; "Honors in English," 1882–1883; and "Honors in French," 1883–1884. In 1886 he received the degree of Master of Arts from the same institution.

In the fall of 1884, having decided to make Civil Engineering his life work, he entered the Massachusetts Institute of Technology, in Boston, Mass. He was graduated in 1887 with the degree of Bachelor of Science in the Department of Civil Engineering, his graduation thesis being "The Fine Grinding of Cement," in partnership with W. S. Thompson, later division engineer of the Sunbury Division of the Pennsylvania Railroad. It was one of the two theses mentioned in the President's (Gen. Francis A. Walker) Annual Report for 1887 as a contribution to knowledge through research, and the results were used by the late George F. Swain,[2] Past-President and Hon. M. Am. Soc. C. E., then Hayward Professor of the Department of Civil Engineering, in a report to the Society in 1887. The other thesis mentioned by General Walker was that of the late J. Waldo Smith,[3] Hon. M. Am. Soc. C. E., the builder of New York's Catskill water supply system.

At the Commencement exercises at the University of New Brunswick in 1922 Mr. Cushing was the alumni orator and was awarded the honorary degree of Doctor of Laws.

Mr. Cushing left Boston the day after graduation, on May 31, 1887, for Louisville, Ky., where he was engaged for service by George W. Kittredge, Hon. M. Am. Soc. C. E., division engineer, as an assistant in the Maintenance of Way Department of the Louisville Division of the Pennsylvania Railroad System. He held this position until January, 1889, when he became engineer, Maintenance of Way, on the Cincinnati and Muskingum Valley Railway (later the Zanesville Branch of the Pittsburgh Division). From August, 1890, until May, 1894, Mr. Cushing was division engineer on the Indianapolis (later Columbus) Division. From 1894 until December 31, 1900, he held the same position on the Pittsburgh (later Panhandle) Division. During the year 1901 he was superintendent of the Pittsburgh Division. This was followed by a year as superintendent of the Eastern Division. Each of these changes was a promotion, as each division to which Mr. Cushing was assigned as engineer or superintendent was more important than that from which he was brought.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 1476.

[3] For memoir, *loc. cit.*, Vol. 101 (1936), p. 1502.

On January 1, 1903, he became chief engineer, Maintenance of Way, on the Southwest System, and on June 1, 1918, was appointed to a similar responsibility on the entire Pennsylvania Lines West of Pittsburgh.

In February, 1920, when the Pennsylvania Lines West of Pittsburgh was merged with the Pennsylvania Railroad Company, Mr. Cushing was transferred to Philadelphia, Pa., as engineer of standards of the Pennsylvania Railroad Company. He held this position until his retirement on June 1, 1932.

Mr. Cushing's life was one of brilliant accomplishment at all stages of his career. During his long service with the Pennsylvania Railroad he was in responsible charge of many important construction projects, such as enlarging and improving facilities by building additional main tracks, separating grades at street and railway crossings, rectifying alinement and grade, designing yards, constructing buildings, stations, and shops, and was engineer-physicist in the study and preparation of specifications for materials and appliances. In his position as division superintendent, he was in charge of all work performed on his division in construction, maintenance, and operation.

He was honored with appointment as a delegate representing the Pennsylvania Railroad Company at the following sessions of the International Railway Congress Association:

1905—Seventh Session, Washington, D. C.
1910—Eighth Session, Berne, Switzerland.
1922—Ninth Session, Rome, Italy, where he was Reporter for America (North and South) on Question III, "Special Steels."
1925—Tenth Session, London, England, where he was Reporter for America (North and South) on Question II, (A) Breaking of Rails and (B) Joints.

Mr. Cushing held membership in the following technical and scientific societies: American Railway Engineering Association, of which he was a charter member in 1889 and president in 1911–1912; Société des Ingénieurs Civils de France; The Institution of Civil Engineers (Great Britain); and The Franklin Institute, in Philadelphia. At the time of his death he was serving on the Committee on Science and Arts of The Franklin Institute.

Following is a list of the technical papers of which he was the author or translator, with the date when each work appeared:

1. "Method of Procedure in Remodeling Yards," *Railroad Gazette*, January 4, 1901.
2. "A New Yard Design," *Railroad Gazette*, March 13, 1903.
3. "Progress in Yard Design," *Railroad Gazette*, May 12, 1905; and *Proceedings*, American Railway Engineering Association, Vol. 7, 1906, and Vol. 9, 1908.
4. English Translation of "Étude sur les Déformations des Voies de Chemins de Fer et les Moyens d'y Rémédier," par M. G. Guënot, published by *Railroad Gazette*, 1907.
5. "The Life of Steel Ties," *Railroad Age Gazette*, June 5, 1908.
6. "The Question of Screw Fastenings to Secure Rails to Ties," *Proceedings*, American Railway Engineering Association, Vol. 10–2, 1909.

7. "Track Superstructure of German Railways," *Proceedings,* American Railway Engineering Association, Vol. 11–2, 1910.
8. "Protecting and Waterproofing Solid Floor Bridges," *Proceedings,* American Railway Engineering Association, Vol. 12–1, 1911.
9. "A Study of Forty Failed Rails," *Proceedings,* American Railway Engineering Association, Vol. 12–2, 1911.
10. "The Question of the Improvement of Rail Design and Specifications from 1893 to the Present Time," *Proceedings,* American Railway Engineering Association, Vol. 13, 1912.
11. "Some of the Causes of Rail Failures," *Proceedings,* American Railway Engineering Association, Vol. 17, 1916; and *Minutes of Proceedings,* The Institution of Civil Engineers (London), Vol. CCI, 1915–1916, Part 1 (awarded "Manby Premium").
12. "Examination of Rails Long in Service for Relation between Internal Stresses and Strains and Transverse Fissures," *Proceedings,* American Railway Engineering Association, Vol. 21, 1920.
13. "Special Steels," *Proceedings,* American Railway Engineering Association, Vol. 17, 1916; and International Railway Association, Ninth Congress, Rome, 1922.
14. "On the Question of Breaking of Rails; Joints" (Subject II for Discussion at the Tenth Session of the International Railway Congress Association); also *Bulletin* of the International Railway Congress Association, Vol. VI, No. 10, October, 1924.
15. "Rail and Wheel"—
    - Part I—"Review of Mathematical and Technical Analysis Applied to Rail Design" (prepared for London Session, 1925, of International Railway Congress Association).
    - Part II—"A Critical Survey of the Physical Requirements for Steel Rails."
    - Part III—"The Genesis of the Transverse Fissure" (American Railway Engineering Association *Bulletin No. 315,* March, 1929).
    - Part IV—"The Heat-Treated Rails in the Tracks" (American Railway Association *Bulletin No. 324,* February, 1930).
    - "Comparison Drawings of Standard Rail Sections," *Proceedings,* American Railway Engineering Association, Vol. 25, 1924, p. 409.

After Mr. Cushing was retired from active service with the Pennsylvania Railroad, he lived a quiet but by no means inactive life in Germantown, a suburb of Philadelphia, where he was doing continuous study and research with The Franklin Institute and other scientific agencies, all with a view to making the world a better place because of his having passed through.

Being very methodical in all that he did, much time in his later years was spent in arranging his personal affairs so that all would be in order when he should be called to leave.

Each year he made a trip to his birthplace, St. John, New Brunswick, to visit with relatives and friends. On many of these trips he visited some of the older family seats in and around Hingham, Mass., and at the time of his death was engaged in collecting data with a view to bringing up to date the genealogy of the Cushing family, the last edition of which was published in 1903.

During his entire life he never missed an opportunity to help a younger engineer or to give credit to an older man who had assisted him. The writer's father was a civil engineer in Canada, and only a few years ago Mr. Cushing produced some papers showing how the writer's father had been helpful to him in his early years. The writer is indebted to Mr. Cushing for obtaining for him his first position in engineering in the United States, when his efforts resulted in the writer's appointment as draftsman and checker on bridges for the Pennsylvania Lines West of Pittsburgh in 1913.

William Cushing was married at Indianapolis, Ind., on February 14, 1894, to Marie Bacon Dye, daughter of John T. and Annie (Glenn) Dye of Indianapolis. He is survived by his only daughter, Annie Theodosia (Mrs. Thomas P. Haviland), and a sister, Emma Helen (Mrs. Alexander Wilson).

A fitting closing for this very inadequate narrative is a sentence from a letter addressed by Mr. Cushing's daughter to the writer on January 29, 1940. Referring to her father, she writes: "He was the most unselfish man that ever lived, and the most wonderful father to me."

Mr. Cushing was elected a Junior of the American Society of Civil Engineers on June 5, 1889; an Associate Member on November 4, 1891; and a Member on May 1, 1901.

CORNELIUS MARK DAILY, M. Am. Soc. C. E.[1]

DIED NOVEMBER 25, 1938

Cornelius Mark Daily, the son of John and Mary Daily, was born on February 23, 1876, in Rolla, Mo. He attended a country school near Rolla and entered the Missouri School of Mines and Metallurgy at Rolla, in 1898, from which he received the degree of Bachelor of Science in General Science in 1902, and the degree of Bachelor of Science in Civil Engineering in 1903.

He served with the U. S. Engineers from 1903 to 1905, first as a surveyman and then as junior engineer on river improvement on both the Mississippi and Missouri rivers. After a brief term as transitman with the St. Louis and North Arkansas Railway Company, he became resident engineer in charge of the installation of machinery in a phosphate mill in Tennessee. After this work was completed, he became associated as assistant engineer with Edward Flad and Company, consulting engineers of St. Louis, Mo., and for the next three years was engaged in the design and construction of such structures as railway yards, shops, retaining walls, water works, and drainage systems.

In 1909 he severed his connection with Edward Flad and Company, and, with Mr. Beckelheimer, formed the firm of Daily and Beckelheimer, consulting engineers, with headquarters in Carmi, Ill. During the next three years he followed a general consulting practice, embracing special investigations and reports, the supervision of a paving project, and the preparation of numerous plans and specifications for roads, drainage districts, and bridges.

---

[1] Memoir prepared by Francis T. Cutts, M. Am. Soc. C. E.

In April, 1911, the firm of Daily and Beckelheimer was dissolved, and Mr. Daily became associated with Pitzman's Company of Surveyors and Engineers as engineer in charge of the construction of a railway incline and protective dike work on the Mississippi River. Upon the completion of this project in January, 1913, he returned to Edward Flad and Company on a special investigation and preliminary plans of slime disposal works for the lead producing companies in the vicinity of Flat River, Mo. In April, 1913, he was appointed assistant engineer, Supply and Purifying Section, St. Louis Water Division, and was engaged in the design of the head-house and other structures that were to be constructed in connection with the Chain of Rocks (Mo.) Filter Plant. On the completion of these designs in November, 1913, Mr. Daily again became associated with Edward Flad and Company in charge of an investigation, survey, and plans for a new water supply for the city of Little Rock, Ark.

In March, 1914, Mr. Daily resumed his position with the Supply and Purifying Section of the St. Louis Water Department as assistant engineer, and was in charge of the operations of the filter plant at Chain of Rocks during the first months of its operation. In 1917 he was made engineer in charge of the Supply and Purifying Section of the St. Louis Water Works.

As engineer in charge of the St. Louis Water Works, Mr. Daily was responsible not only for the operation and maintenance of the supply and purifying division, but also for the design and construction supervision of the new buildings and other structures in connection with the building of the new St. Louis Water Works plant at Howard Bend on the Missouri River. In 1925 he resigned to engage in a general engineering and contracting business, and continued in this business until April, 1932, when he was offered, and accepted, the appointment as water commissioner for the City of St. Louis.

Mr. Daily's earlier professional training and his previous connections with the St. Louis Water Works well qualified him for the position, which he filled with great credit to his profession. In the fall of 1935 he resigned as water commissioner to become identified with the construction industry again, and from that time until his death he was engaged in the construction of many important projects.

Mr. Daily died suddenly in Jacksonville, Ill., on November 25, 1938. He was recognized as an authority in the design and construction of water works. He was a member of the Engineers' Club of St. Louis and the American Water Works Association, and contributed frequently to various technical publications.

On June 19, 1901, Mr. Daily was married to Margaret O. Miller, of St. Charles, Mo., who, with one daughter, Marian Dorothy (Mrs. P. J. Hill), and one son, Austin E. Daily, survives him.

He lived a useful life, and was untiring in his efforts. His loyalty, honesty, and ability were well recognized by all who knew him.

Mr. Daily was elected a Member of the American Society of Civil Engineers on September 11, 1917.

JOHN VIPOND DAVIES, M. Am. Soc. C. E.[1]

DIED OCTOBER 4, 1939

John Vipond Davies was born at Swansea, Wales, on October 13, 1862, the son of Andrew and Emily (Vipond) Davies. He received his education at Wesleyan College, Taunton, England, and at the University of London, London, England.

He worked in Wales as an engineer in the British coal mines and in the manufacture of steel until 1889, when he came to New York, N. Y., on the invitation of the late Charles M. Jacobs,[2] M. Am. Soc. C. E., with whom he later formed the partnership of Jacobs and Davies. In this earlier association Mr. Davies was employed by the Long Island Railroad Company, then under the presidency of Austin Corbin, when Mr. Jacobs was evolving some of the first proposals to connect this railroad with the Pennsylvania Railroad at Jersey City, N. J.

Mr. Davies acted as chief assistant engineer to Mr. Jacobs during the construction of the East River Gas Company tunnel under the East River and Blackwells Island, the first tunnel to pass under any of the harbors of the port of New York.

After the completion of the tunnel in 1893 Mr. Davies and Mr. Jacobs formed the partnership of Jacobs and Davies. Their first assignment was the construction of a pumping plant for the Montauk (N. Y.) Water Company capable of delivering 2,000,000 gal of water per day from artesian wells to the Long Island Railroad.

During the following few years Mr. Davies devoted most of his time to railroad construction. He was chief engineer in entire charge of design and construction of the West Virginia Short Line, the Kanawha and Pocahontas Railroad, and the Atlantic Avenue improvement of the Long Island Railroad, which included 2½ miles of subway and 3 miles of viaduct with the terminal facilities. In 1901 the firm made additional studies when plans were revived to extend the Pennsylvania Railroad into New York City and beyond to Long Island.

In 1902 the firm undertook the project of completing what was later the north uptown tunnel (partly built by De Witt Haskins and also by Pearson and Sons) of the Hudson and Manhattan Railroad and "holed" it through in 1904, completing the first tunnel under the Hudson River at New York. This tunnel was the nucleus of what eventually became the extensive interurban transit system of the Hudson and Manhattan Railroad, with its four tunnels under the Hudson River connecting the main railroads of New Jersey with downtown and uptown New York.

In October, 1909, the firm of Jacobs and Davies was incorporated and continued the extensions of the Hudson and Manhattan Railroad to Newark,

---

[1] Memoir prepared by James Forgie, M. Am. Soc. C. E., and collaborators.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–1920), p. 2236.

N. J., and 33d Street, New York, under the supervision of Mr. Davies as chief engineer. He then became president of his firm, and later chief engineer, vice-president, and a director of the Hudson and Manhattan Railroad Company.

Subsequent to 1909 the firm executed much of the design and construction by its own administration of the following major projects: Hales Bar Dam on the Tennessee River about 20 miles south of Chattanooga, Tenn.; the 20 miles of tunnels, canalage, and intakes of the Laxaxalpam Aqueduct feeding the electric power plant of Necaxa of the Mexican Light and Power Company, about 100 miles northeast of Mexico City, Mexico; the large and hazardous tunnel construction of the Consolidated Gas Company of New York under Hell Gate from its plant in Astoria, Long Island City, N. Y., to 135th Street, Bronx County; also engineering supervision of contract work of the terminal improvement work of the New York Central Railroad Company during the excavation of the site of the Grand Central Station.

Mr. Davies was engaged as consulting engineer for the Brooklyn Rapid Transit Company; the water supply tunnel under the Detroit River for the City of Detroit, Mich.; acted as a member of the board of engineers on the construction of the Moffat Tunnel in the Rocky Mountains near Denver, Colo.; executed construction of the power station intake and discharge tunnels of the New York Edison Company; member of the board of consulting engineers in study and report on a bridge or tunnel crossing the Mississippi River at New Orleans, La.; the New York State Bridge and Tunnel Commission and the New Jersey Interstate Bridge and Tunnel Commission in preliminary studies for a Hudson River highway crossing, which eventually became the Holland Tunnel; he served as a member of the board of consulting engineers during construction—in all, this association covered the period from 1912 to 1922. He made collaborative studies and a report on the proposal for a bridge or tunnel across San Francisco Bay, from San Francisco to Oakland.

John Vipond Davies was a Charter Member of American Institute of Consulting Engineers, and one of the early group of engineers, led by the late Alfred P. Boller,[3] M. Am. Soc. C. E., responsible for the initial organization of the Institute, and the influential and recognized standing of the organization several years in advance of its legal incorporation in 1913.

Mr. Davies was a member of The Institution of Civil Engineers, the American Institute of Mining and Metallurgical Engineers, and president of United Engineering Societies from 1920 to 1923.

He was particularly interested in a Code of Ethics, which should apply in the engineering profession, and a schedule of fees for engineering work. From 1921 until his death he was a member of the committee on Professional Practice and Ethics of American Institute of Consulting Engineers. His advice on this committee was greatly appreciated. In 1929 he served as chairman of a special Committee appointed by the American Society of Civil Engineers on "Charges and Methods of Making Charges for Professional Services." This committee made an elaborate report which was approved by the Board of Direction on July 9, 1939.

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1653.

In 1914 he was awarded the Telford Gold Medal of The Institution of Civil Engineers; the Norman Gold Medal, in 1913, and Thomas Fitch Rowland Prize, in 1917, of the Society; also the Fowler Professional Award in 1930.

Socially he was president of the St. George's Society of New York for the year 1922–1923; president of the Oakland Golf Club, 1914–1919; member of the Pilgrims of the United States, the Engineers' Club, and Railroad Club of New York, of which he was for many years a member of the Board of Governors.

In 1895 he was married to Ruth Ramsey of Pottsville, Pa., who died in 1931. He is survived by two daughters, Margaret (Mrs. C. Olden Davis) and Muriel (Mrs. Malcolm Mackenzie), and a son, J. Vipond Davies, Jr.

Mr. Davies was a man of great energy and courage and risked his life to stop a team of runaway horses from trampling small children. He was dragged for some distance and badly bruised, with the result that he was confined to bed for several weeks.

He was deeply loved and respected by the executive staff and employees of the Hudson and Manhattan Railroad Company, with which his association covered a period of 37 years, and by many others who worked with him or under his direction.

Mr. Davies was elected a Member of the American Society of Civil Engineers on June 6, 1894.

DANIEL YOUNG DIMON, M. Am. Soc. C. E.[1]

Died July 8, 1939

Daniel Young Dimon was born at Riverhead, N. Y., on March 22, 1874. He was the son of John M. and Adelia (Young) Dimon. The Dimon family were early settlers in Riverhead, and Daniel's father was a prosperous farmer during the son's formative years.

Daniel's early life was spent in Riverhead where he was educated in the local public schools. He was graduated from Riverhead High School in 1892. He then spent four years at Cornell University, at Ithaca, N. Y., and was graduated *magna cum laude* with the degree of Civil Engineer in June, 1896.

Immediately following graduation he entered the employ of the Groton (N. Y.) Bridge Company where he had four years of practical formative training in detail drafting, shop and field inspection, and estimating and designing work. Thereafter he followed the career of a structural engineer.

From June, 1900, to September, 1903, he was employed by the American Bridge Company in its Designing Department at Pencoyd, Pa., where he had responsible charge of designing and estimating steel work of highway and railway bridges, buildings, cranes, etc. Subsequently he was employed in the

---

[1] Memoir prepared by Joseph H. O'Brien and Fenwick F. Skinner, Members, Am. Soc. C. E., and Lorenzo C. Dilks, Assoc. M. Am. Soc. C. E.

Designing Department of Milliken Brothers, in New York, N. Y., in charge of design of steel bridge work and steel work of mills and office buildings.

From October, 1904, until 1909 he was employed by Westinghouse, Church, Kerr and Company as office engineer in charge of design under the resident civil engineer of Pennsylvania Terminal improvements in New York City. His work included the design of foundations for the Terminal Station building and surrounding street viaducts, East River tunnel approaches, etc., and the design of all substructures including baggage tunnels, elevator pits, pipe and wire tunnels, underground duct systems, drainage system, etc.

Mr. Dimon then became associated with the Eastern Steel Company as assistant engineer until 1915. He was employed as structural engineer by Milliken Brothers from 1915 to 1917, by the Downey Shipbuilding Corporation from 1917 to July 15, 1918, and by the Foster Wheeler Corporation thereafter until March 26, 1921, when failing eyesight caused him to abandon pursuit of his profession for about two years. He was again employed by Foster Wheeler Corporation in the spring of 1923 and subsequently for two years by the J. G. White Engineering Corporation. This engagement was followed by association with John K. Turton and Company for a period of one year, and association with George A. Fuller Construction Corporation for the period from 1926 through 1929.

From February, 1930, to June, 1938, he was employed by Gibbs and Hill, Inc., as structural engineer in responsible charge of the design of structural steel work for the New York Post Office building on the Pennsylvania Terminal site between Ninth and Tenth Avenues. He was also in charge of structural work connected with important changes made in the 31st Street viaduct and in supports of the original Post Office building at the Terminal site incidental to changes in track layout. He also collaborated in the design of certain important structures in connection with electrification of the Pennsylvania Railroad in the New York zone, and had charge of the design of structural steel for the superstructure of Newark Terminal station improvements for the Pennsylvania Railroad Company, and the structural steel work of certain important power plants for the New York, New Haven and Hartford Railroad Company.

He was employed by the Board of Water Supply for the City of New York from June 1, 1938, until his death.

Mr. Dimon was a brother of the late Henry Dimon, a widely known member of the staff of the American Bridge Company at the time of its formation.

Mr. Dimon, who was highly esteemed by his associates, was a structural engineer of rare ability. He was conscientious, loyal, well poised, and possessed of a real sense of humor; he was ever careful, painstaking, and strong in his determination to perform the work assigned to him in accordance with the best engineering practice. He served his profession well and honorably.

On August 24, 1897, Mr. Dimon was married to Huldah Ann Taft of Riverhead who survives him, as do their three children, Daniel Young Dimon, Jr., John T. Dimon, and Margaret Dimon (Mrs. Benjamin Fisher).

Mr. Dimon was elected an Associate Member of the American Society of Civil Engineers on October 2, 1901, and a Member on March 31, 1908.

WALTER ALEXANDER DOANE, M. Am. Soc. C. E.[1]

Died January 28, 1940

At the time of his death only five living men had been members of the Society, in any grade, longer than Walter A. Doane. He was the son of Isaac S. and Elizabeth (Morse) Doane, and was born in Ellicottville, N. Y., on September 17, 1854.

When he was 10 years old the family settled in East Mead Township, near Wayland. He was educated in the public schools, and then attended for a period a civil engineering college in Connecticut. At the age of 17 young Doane started to work for his father (some time city engineer of Meadville, Pa.) on the Lake Shore Railroad, later known as The Rome, Watertown and Ogdensburg Railroad, and finally a part of the New York Central Railroad system. Mr. Doane was a draftsman and assistant engineer on location from April, 1871, to December, 1873, at which time he became a division engineer in charge of construction. He held this position until September, 1876. It is interesting to recall that, at this time, the late James Ross, M. Am. Soc. C. E., a young Scot, obtained his first job in America on the staff of Walter A. Doane's father and took a liking to young Doane. Mr. Ross proved a remarkably good judge of men, as well as capable in his own right—so much so, that, when he died in 1913, he was reputed to have left an estate of 14 million dollars.

In March, 1878, Mr. Doane accepted the position of chief engineer of the Lehigh and Eastern Railway Company, which position he held until August, 1880, running preliminary lines and location. On August 1, 1880, he started work as principal assistant engineer of the Meadville-Conneaut Lake and Linesville Railroad Company (under his brother Alonzo Doane), which position he held until October, 1880, when he was promoted to the position of chief engineer. The Meadville-Conneaut Lake and Linesville Railroad was completed in 1881 or 1882, permitting Mr. Doane to accept a position as chief of party on the location, in Kansas, of the Santa Fe Railway.

Early in 1883 James Ross, who had just been appointed manager of construction of that section of the Canadian Pacific Railway from Maple Creek, Saskatchewan, some 90 miles east of Medicine Hat, Alberta, to, and through, the Rocky Mountains and over the Selkirk Mountains in British Columbia, sent for Mr. Doane and installed him as his bridge engineer on the Rocky Mountain section. The first office, in May, 1883, was in a tent at Medicine Hat; in August quarters were moved to Calgary, Alberta. On Mr. Doane's staff, from the start, were P. Turner Bone and the writer.

In 1884–1885 Mr. Doane's office was at Laggan, Alberta, the summit of the pass through the Rocky Mountains. In 1884 George Herrick Duggan (later Hon. M. Am. Soc. C. E., and chairman of The Dominion Bridge Company at Montreal, Quebec) joined his staff. The bridges were all of timber, cut and squared at the sites. In those days no steel was available. The only iron used consisted of bolts and rods, with cast-iron angle blocks for the Howe trusses; these materials came from Chicago, Ill.

---

[1] Memoir prepared by T. Kennard Thomson, M. Am. Soc. C. E.

It is doubtful if any engineer had a greater knowledge of the design and construction of wooden bridges than Mr. Doane. Among the structures of this type that he built for the Canadian Pacific Railroad were: The first one over the South Saskatchewan River at Medicine Hat; one over the Bow River at Calgary; many over the Kicking Horse and other rivers in the Rocky Mountain and Selkirk Mountain ranges, including one over Stony Creek (probably the highest wooden trestle, with Howe trusses, in the world); Mountain Creek trestle, a very long and fairly high structure; and Surprise Creek, Cedar Creek, and many other bridges. The notes made by the writer at the time, showing most of these designs, have been presented to the Society. Of course, all of these wooden bridges which had been built in advance of the railroad track were replaced by iron, in time, and these in turn were replaced by steel structures, as the traffic, engines, and cars became heavier and demanded stronger bridges.

On the completion of the Canadian Pacific Railway from Montreal to the Pacific Ocean, in November, 1885, it became the first complete transcontinental road in America; in fact there is still none in the United States under one management. His work finished, Mr. Doane then accepted a position on the Oregon, Washington Railroad and Navigation Company. He acquired the habit here, or possibly earlier, of buying real estate as he moved from place to place. From the start, however, he wisely realized that it does not pay to hold undeveloped land, so his plan was to erect buildings at once which he could rent.

From January, 1890, to the end of 1893 Mr. Doane was principal assistant engineer under the late W. W. Coe,[2] M. Am. Soc. C. E., for the location and construction of the Ohio Extension (to the Ohio River at Kenova, W. Va.) of the Norfolk and Western Railway, later a part of the Pennsylvania Railroad system. The town of Kenova took its spelling from parts of the three surrounding states' names—Kentucky, Ohio, and West Virginia. The Ohio Extension of the Norfolk and Western Railway, built for heavy coal traffic, was on a very difficult location, crossing and recrossing rivers (especially the Big Sandy) many times. It required sharp (12°) curves and steep grades. It is interesting to note that, some 30 or more years later, an up-to-date electric railroad was not able to find a much, if any, better location.

On this line there were 129 iron bridges. Steel was not yet accepted, and for a long time was not considered as safe as iron except for such important members as eyebars. Among these bridges was a large one over the Ohio River at Kenova, with four spans of 300 ft each, one of 520 ft, and a long viaduct approach in Kenova. At this site the low-water depth was 6 ft, and the high water depth, 66 ft. Several severe floods occurred during construction with very little advance warning, so great pains were taken for rapid erection. As a result, the iron was erected so that the falseworks for the 300-ft spans could be removed in three and a half days, and for the 520-ft span in fifteen days—which was quite a record for that time. The bridge was reconstructed[3] for double track in 1912–1913. The Kenova Bridge (Ohio Extension, Norfolk and Western Railway) iron work was designed originally for single track, but the trusses were spaced far enough apart to permit inserting a middle truss later. The foundations and piers also were designed for the future, but when double tracking was decided on, all of the trusses were replaced, using the old piers as originally built.

---

[2] For memoir, see *Transactions*, Vol. LXXXIII (1919–1920), p. 2175.

Although he was a great authority on the design and construction of wooden bridges, Mr. Doane modestly did not claim to be a designer of iron bridges; so he again called on his former associate, the writer, who was then with the Pencoyd Bridge Company, near Philadelphia, Pa., and honored him by an appointment as bridge engineer for the Ohio Extension of the Norfolk and Western Railway. The office, for a short time early in January, 1890, was at the Roanoke, W. Va., headquarters of the Norfolk and Western Railway; then it was moved to a new building in Kenova, the town being merely an undeveloped site extending from Ceredo, W. Va., to the Big Sandy River.

This work demonstrated, as did all of his other work, one of Mr. Doane's sterling characteristics—that he was always courteous and just in his treatment of contractors; and although he was as lenient as he could be, he always insisted on, and obtained, first-class work for his clients. In the early eighties most engineers thought it necessary to swear at contractors, and similarly the contractors did not think that they could manage their men otherwise; but Walter A. Doane always succeeded without the use of profanity. He did not smoke or even drink tea or coffee (another very unusual trait for an engineer in those days); yet he had an active life for 85 years.

From 1893 to 1905 Mr. Doane was city engineer for the City of Meadville, as his father had been before him. He also "acted as city engineer" for several years, in the same city, at a later period. Following this work, in 1905–1907, Mr. Doane was principal assistant engineer in charge of construction of the Carolina, Clinchfield and Ohio Railway.

For the thirty-three remaining years of his life, Mr. Doane maintained his office in Meadville under the name of Walter A. Doane and Son, Consulting and Practicing Engineers. As his son, Arthur W., carries on the business with its valuable records, he perpetuates three generations of engineers by the name of Doane in the city of Meadville.

For more than half a century Mr. Doane honored the writer with several letters a year, the last of which was written on January 16, 1940, when he wrote that he was feeling well and active at 85. He added that he was still using, to prick holes in drawing paper instead of making a pencil point, a piece of white (Rocky Mountain) pine in which had been inserted a needle before it had been shaved down to the size of a pencil. He recalled that the writer had made this for him 57 years before, while on the Canadian work.

---

[3] For description of reconstruction, see *Transactions*, Am. Soc. C. E., Vol. LXXIX (1915), p. 411.

On January 20, 1940, Mr. Doane suffered what was considered to be a slight stroke, from which, in spite of his hopeful optimism, he failed to recover. He died on January 28, 1940.

He was a life member of The Renovation Lodge, Free and Accepted Masons of Albion, N. Y., and belonged to the Meadville Grange, in which he was very active. He was, as in everything else, a faithful member of the Stone Methodist Church, in Meadville, and of the Men's Bible Class. Mr. Doane wrote and published two delightful books of poems, relating to human nature, to his friends, to his family, and to the surrounding country. His writings are evidence of the kindly, home loving, and devoted nature of a sterling man. He wrote about the small intimate things around him, giving them the importance that they deserved. He was proud of the history and the traditions of his home community, which are enriched by these poems.

In physique, he was wiry, strong, and active. As to character, he was absolutely reliable in everything he said or did, true and devoted to his family, his friends, his country, and his church, as well as to the engineering profession and the Society of which he was so proud. Everything Walter A. Doane ever did was well and carefully done.

On May 11, 1882, he was married to Harriet Louise Ellis of West Mead Township, Pa., who was his devoted wife for forty-four years. She died in 1926. Mr. Doane is survived by their four children, Ethel Doane, Morse E. Doane, Arthur W. Doane, and Norman D. Doane. He is also survived by a brother, Dr. L. L. Doane; a sister, Mrs. Mae D. Washburn; a grandchild; and several nieces and nephews.

It is a great achievement to have lived a long and useful life and at the end of 85 years to be esteemed by all as among the foremost of worth-while and respected citizens. Walter A. Doane deserves, as few others have, the epitaph:

> "The memory of a life nobly rendered is immortal."

Mr. Doane was elected a Member of the American Society of Civil Engineers on September 7, 1881. He remained a loyal and enthusiastic member for the remainder of his life.

GUY CARLETON EMERSON, M. Am. Soc. C. E.[1]

Died July 17, 1939

Guy C. Emerson was born on March 12, 1867, at Orland, Me. He was a descendant of Michael Emerson, who was an early settler of Haverhill, Mass.

After graduation from the Eastern Maine Conference Seminary at Bucksport, he prepared at Chauncy Hall School in Boston, Mass., for Massachusetts Institute of Technology (M. I. T.), at Cambridge, Mass. He entered M. I. T.

---

[1] Memoir prepared by Charles W. Sherman and Charles R. Gow, Members, Am. Soc. C. E.

in 1886 and remained for three years, taking the course in civil engineering.

In 1889 the construction of the (Boston) Metropolitan Sewerage System was begun, with the late Howard A. Carson,[2] Hon. M. Am. Soc. C. E., as chief engineer, and Mr. Emerson was given work on the engineering staff. He found this more to his liking than the completion of his course at M. I. T., and remained on the sewerage work as rodman, assistant, transitman, inspector, and assistant engineer, until the original works were substantially completed in 1895. At that time Mr. Carson became chief engineer of the Boston Transit Commission, charged with the construction of the Boston subways—the first structures of their kind in America. Several of the assistant engineers who had been employed on the Metropolitan Sewers accompanied Mr. Carson, among them Mr. Emerson, who became assistant engineer in charge of inspection. Throughout the construction of the original subway he had complete charge of all construction matters in the field. Since the work was the first of its kind ever done in the United States, many of the construction problems were unique and unprecedented, and to Mr. Emerson belonged much of the credit for working out the various methods of procedure adopted in prosecuting the work.

On the completion of the original subway in 1898, the engineering staff was disbanded, and he entered into a partnership with the late E. A. Clark, with the idea of conducting a contracting business. This partnership continued for about two years, but did not obtain any contracts of significance.

In 1900 Mr. Emerson was appointed superintendent of sewers of the City of Boston. At that time all the public works activities of the city were under the control of a superintendent of streets; the late B. T. Wheeler,[3] M. Am. Soc. C. E., held the office at that time, and Mr. Emerson was in charge of the Sewer Division under Mr. Wheeler's general direction. He was designated as deputy superintendent of streets, and for a few months was acting superintendent of streets.

Following a change in administration in 1902, he was replaced, but soon afterward became chief engineer of the Montreal (Quebec, Canada) Subway Company and had charge of surveys, plans, and specifications for tunnels under the St. Lawrence River and subways in city streets. This work lasted about a year, after which he returned to Boston and maintained an office as consulting engineer for about two years.

In August, 1906, he became construction engineer for the Bureau of Reclamation, in charge of one of the original units of the Shoshone Project, located at Powell, Wyo. The work in his charge was the so-called Corbett tunnel, 3½ miles long. In addition to the engineering work, it became necessary for him to act as police chief, postmaster, town clerk, and town treasurer. It has been said that his official connection with the Bureau of Reclamation in its early days was a contributing factor in the necessary pioneer work preliminary to the later extensive program. The "town" was essentially a construction camp, and at that time the necessity of adequate sanitary precautions in such places was not generally recognized. As a result, typhoid fever became prevalent in the camp, and Mr. Emerson was stricken with it shortly before the completion of the job. He resigned his position in December, 1907, and returned to Boston.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1386.

[3] For memoir, *loc. cit.*, Vol. 93 (1929), p. 1919.

After recovering his health, he was appointed in 1908 as superintendent of streets of Boston, but after a year or two a change of administration resulted in his giving up this position. Soon thereafter he was appointed as consulting engineer to the Boston Finance Commission which, under a new city charter, had then been established on a permanent basis, in succession to a temporary body having the same title, which had just completed a 2-yr investigation of the operations of various city departments. This work did not require all his time, and he was able to take other employment. During the next few years he had some other professional engagements, and from time to time he was consulted by other municipalities seeking advice with respect to construction methods and policies. Perhaps the best known of his engagements, other than for the City of Boston, was as engineer of a special commission appointed by the Massachusetts Legislature in 1912 to investigate the water supply needs of certain cities, especially Salem and Beverly. He continued in the service of the Finance Commission until his retirement in 1936.

Mr. Emerson's engineering mind was distinctly of the constructive and creative type rather than of a theoretical character; that is, he was inclined to interest himself in the creative aspects of engineering rather than in analytical and research investigations, and it was in this field that he met his greatest degree of success.

He was a member of the Boston Society of Civil Engineers and the New England Water Works Association. He was interested in the early history of Boston, and was a life member of the Bostonian Society. He was also a member of the Boston City Club.

He is survived by his wife, Perpetia Lillian (Talbot) Emerson.

Mr. Emerson was elected a Member of the American Society of Civil Engineers on May 4, 1904.

JOHN FARRIS, M. Am. Soc. C. E.[1]

DIED APRIL 15, 1939

John Farris was the son of William and Susan (Nixon) Farris, who came to America from Ireland when they were children. He was born in Fennimore, Wis., where he spent his boyhood and received his early education, graduating from the Fennimore High School. In 1901 he was graduated from the Platteville (Wis.) State Normal College.

---

[1] Memoir prepared by Arch W. Nance and Carl J. Jacobsen, Associate Members, Am. Soc. C. E.

His first position was as instructor in science and mathematics in the high schools of Monroe, Wis. In 1905 he entered the University of Wisconsin, at Madison, Wis., and taught in the Wisconsin Academy until his graduation from the University in 1907.

He then joined an older brother as a partner in the Farris Bridge Company, with offices in Pittsburgh, Pa., and Charleston, W. Va. The firm engaged in bridge construction in Pennsylvania, West Virginia, Maryland, and Kentucky.

During 1908 and 1909, Mr. Farris attended the University of Pittsburgh, and received the degree of Civil Engineer. While at the University he designed a set of standards for steel highway bridges varying (in 5-ft lengths) from 40 ft to 200 ft, with both varying loadings and widths of roadways.

In 1915, he became president of the Farris Engineering Company, which company has been active, continuously, in bridge construction in the Tri-State territory (Pennsylvania-Maryland-West Virginia). Also, since 1927, he was president of the Mausoleum Construction Company, builders and owners of Mount Royal Memorial Mausoleum, the first and largest structure of its type and purpose to be offered for above-ground entombment in the Pittsburgh district.

He believed in, and worked diligently for, due recognition of the engineer as a public servant, was a past-president of his local section of the American Society of Civil Engineers and a member of the Pennsylvania Society of Professional Engineers. At the time of his death, he was serving his third year as a member of the State Board for Registration of Professional Engineers of Pennsylvania, and his second year on the Board of Governors of the Constructors Association of Western Pennsylvania.

During his extremely active career, Mr. Farris received consultant appointments on bridges and buildings under three state administrations; and at the time of his death he was engineer for the General State Authority on the Western State Psychiatric Hospital in Pittsburgh, completed in 1939.

He was always loyal to his native state and its university, was twice president of the University of Wisconsin Alumni Club of Pittsburgh and represented the University in local activities. Since the death of his father in 1922, he had taken over the old family homestead near Fennimore and operated a modern dairy farm with a herd of registered Jerseys of which he was justly proud.

Fraternal life was also an active field for his talents. He was a Thirty-Second Degree Scottish Rite Mason, a Knight Templar, and a Shriner; he served seven years on the Divan of Syria Temple, Pittsburgh, and was elected Potentate in 1937.

Possessed of a keen sense of humor and ready wit, he made work and play boon companions during his busy life.

Mr. Farris was elected an Associate Member of the American Society of Civil Engineers on August 31, 1915, and a Member on May 12, 1919.

HOWELL TRACY FISHER, M. Am. Soc. C. E.[1]

DIED NOVEMBER 6, 1938

Howell Tracy Fisher was born on December 10, 1868, in Pottsville, Pa., the son of Howell Fisher and Charlotte Anne (Sheafe) Fisher. He attended private and public schools and was graduated from the Pottsville High School.

From 1886 to 1888 he was a rodman, draftsman, and transitman for the Anthracite Geological Survey of Pennsylvania, and his name is upon a great many of the sheets of the map of the anthracite coal fields. In 1888 and 1889 he served in the engineering department of the Susquehanna Coal Company at Wilkes-Barre, Pa., and from 1889 to 1891 he was city surveyor of Pottsville. From 1891 to 1893 he was principal assistant to A. D. W. Smith, geologist and mining engineer in Philadelphia, Pa., engaged in the preparation of reports for the Anthracite Coal Waste Commission and the compilation of a geological map of Pennsylvania. From 1893 to 1898 he was employed by A. B. Cochran and Son, civil and mining engineers and borough surveyors of Pottsville.

In June, 1898, he took a position with the U. S. Board of Engineers and worked on estimates and surveys for a canal for ships from the Great Lakes to the Atlantic Ocean, on surveys in the Mohawk Valley, New York, and on reports in Detroit, Mich. He became associated with the Isthmian Canal Commission in July, 1900, and was occupied, in Washington, D. C., on drawings, maps, and estimates of cost of the Panama and Nicaragua canal routes. From January, 1902, to August, 1902, he was assistant engineer of the Denver Union Water Company on construction of Cheeseman Dam, in Colorado, then the highest stone arch dam in the world. In August, 1902, he became irrigation engineer of the U. S. Geological Survey in charge of reclamation service of the Grand River Canal Project and cadastral surveys in the Gunnsom Project, Uncompahgre Valley, Colorado.

Mr. Fisher became assistant engineer of the East River Division, Pennsylvania, New York and Long Island Railroad Company, and the Pennsylvania Tunnel and Terminal Railroad Company, in January, 1903, and was engaged on the construction of tunnels under Long Island City, N. Y., and the East River, New York, N. Y. In February, 1909, he became assistant to Henry F. Dose, M. Am. Soc. C. E., in Washington, D. C., on plans and estimates for a railroad in Guatemala, and during 1910 and 1911 he was employed by the Delaware, Lackawanna, and Western Railroad Company on the construction of a cutoff line in New Jersey. He was appointed tunnel engineer with Mackenzie, Mann and Company, Ltd., and the Montreal Tunnel and Terminal Company, Ltd., in April, 1912, and worked on the design and construction of 3⅛ miles of tunnel under Mount Royal for the Canadian Northern Railway at Montreal, Quebec, Canada.

---

[1] Memoir prepared by J. Howell Healy, Esq., Philadelphia, Pa.

From 1915 to 1917 Mr. Fisher was in private engineering practice in New York City, but in the spring of 1917 he took the position of resident engineer with the Federal Ship Building Company and superintended the construction of steel ships on the Hackensack River. After completion of the shipyard work, Mr. Fisher was employed by Fraser, Brace and Company in New York City until the spring of 1919, when he retired.

After his retirement from engineering practice, Mr. Fisher became deeply interested in art. He took up painting and without any previous training or experience did very creditable work in oils and water colors. In recent years he had specialized in miniatures, and for the two years prior to his death he was secretary of the Pennsylvania Miniature Society. Mr. Fisher was also a member of the Pennsylvania Historical Society, and found time, in a very busy life, to write a book on the genealogy of his family. This book was presented to the Pennsylvania Historical Society.

Mr. Fisher was married to Lucy Cobb Williams on June 11, 1913, and they made their home in Germantown, Philadelphia. He died very suddenly on November 6, 1938, and is survived by Mrs. Fisher.

Mr. Fisher will be remembered by those who were privileged to know him for his attractive and gracious personality. He was fortunate in arousing the enthusiasm of all who were brought within the sphere of his friendship.

Mr. Fisher was elected an Associate Member of the American Society of Civil Engineers on November 1, 1905, and a Member on January 7, 1913.

LOUIS PREVOST GASTON, M. Am. Soc. C. E.[1]

Died July 14, 1939

Louis Prevost Gaston died unexpectedly at the summer home of his daughter, Mrs. Milton L. Cornell, at Sea Bright, N. J.; he was seized with a heart attack while engaged in conversation with his wife and daughters.

Mr. Gaston was born in Somerville, N. J., on October 17, 1864. His father was Hugh M. Gaston, a former prosecutor of Somerset County and a civic leader at the time of the Civil War. His mother was Frances Mallet-Prevost. Mr. Gaston inherited French Huguenot ancestry on both sides of his family, as well as some Scotch lineage on his father's side.

His early education was received in the Somerville schools; and he was awarded his Bachelor's Degree from Lehigh University at Bethlehem, Pa., in 1888, and his Civil Engineering Degree from the same institution in 1889.

His first position was with Cofrode and Evans, general contractors, with whom he was engaged from the year of his graduation until 1896. He assisted in the construction of various railroad projects, and designed and supervised the construction of two large coal shipping piers for the New York, Susquehanna and Western Railroad at Edgewater, N. J.

---

[1] Memoir prepared by H. G. Van der Veer, President, Richards & Gaston, Inc., Somerville, N. J.

From 1898 until 1900 Mr. Gaston made examinations and submitted reports on numerous water power developments, including the Great Falls of Catawba River, in South Carolina, Lookout Shoals, in North Carolina, and Trenton Falls, New York.

His mature professional career was devoted essentially to the contracting firm of Richards and Gaston which was organized in 1900, and with which he was associated in an advisory capacity at the time of his death. The first large contract awarded to the firm was the repair of flood damage and the construction of bridge piers and abutments for the Central Railroad of New Jersey at Glen Onoko, Weissport, and Allentown, Pa. From 1905 until 1910 the firm was particularly engaged in the construction of bridges, lakes, and ornamental concrete for James B. Duke, President of the American Tobacco Company, on his private estate in Somerville.

In 1910 the partnership of Richards and Gaston became a corporation with Mr. Gaston as president, a position he held until his retirement from active duties in November, 1925. While he was president the corporation completed railroad contracts amounting to more than $2,000,000, including track elevations for the Central Railroad of New Jersey at Cranford and Somerville, four-tracking of the Reading Railroad from Weston, N. J., to Belle Mead, N. J.; additional tracks for the New York Central Railroad at Staatsburg and Poughkeepsie, N. Y.; also bridge and track changes for the Lehigh Valley Railroad at Buffalo, N. Y., and Roycefield, N. J. The firm also participated in New Jersey State Highway bridge and road construction amounting to more than $1,000,000, and constructed roads, sewers, and dams for counties and municipalities.

Mr. Gaston and his partners formed the Lakewood Sand Company of Lakewood, N. J., in 1905, and in 1922 this company was incorporated with Mr. Gaston as president, a position he held until the business was sold in 1927. At one time this company was the main supplier of sand to dealers along the Central Railroad of New Jersey, and this railroad as well as the State of New Jersey used this sand in its concrete construction.

Mr. Gaston designed and patented a narrow-gage railroad dump car (The Eastern Dump Car) for the use of contractors. He organized a company to build these cars, and many were sold to sand and gravel producers. Others were used for coal stripping and contracting in the eastern part of the United States and in South America.

While Mr. Gaston was known and loved in Somerville for his participation in community affairs, the full extent of his quiet philanthropy was known only to himself. Chief among his interests was the Somerset Hospital, in Somerville, to which he gave generously of his time and means. During the later years of his life he was interested in the development of the Somerville Park lands, and one section of this area was developed and equipped at his expense. He was also President of the Somerville Savings Bank, and a member of the Board of Managers of the New Jersey Sanatorium for Tuberculous Diseases at Glen Gardner, N. J.

On September 5, 1896, Mr. Gaston was married to Maude Safford, of Sharon, Mass., the daughter of the late Edward Stanley Safford, M. Am. Soc. C. E., and a member of the first graduating class of the Massachusetts Institute of Technology. She survives him, as do two sisters, four children, and eight grandchildren.

Mr. Gaston was elected a Member of the American Society of Civil Engineers on February 1, 1905.

GEORGE GIBBS, M. Am. Soc. C. E.[1]

DIED MAY 19, 1940

George Gibbs was born in Chicago, Ill., on April 19, 1861, the son of Francis S. Gibbs and Eliza Gay (Hosmer) Gibbs. He came from a family of English descent, his first American ancestor being James Gibbs who came originally from Bristol, England, and settled in Rhode Island about 1660. His family was identified with the history and growth of Newport, R. I., from the earliest times—dating from a few years after the purchase in 1638 from the Indians by Governor Coddington of the Island of Aquidneck, as Newport was then called. James Gibbs and his wife, Sarah, settled in Newport and later moved to Bristol, R. I. George Gibbs was the fifth descendant in the line of this Rhode Island family to bear the name "George."

George Gibbs' great-grandfather, George Gibbs II, was a shipping merchant in trade with the West Indies, China, St. Petersburg (later Petrograd, U. S. S. R.), and the Mediterranean, and controlled a large fleet of vessels operating out of Newport. He was married to Mary Channing of the Rhode Island family of that name. George Gibbs III, grandfather of George Gibbs, was devoted to scientific studies and acquired a very fine collection of minerals, later in the possession of Yale University at New Haven, Conn. He was married to Laura Wolcott, the granddaughter of Oliver Wolcott, Secretary of the Treasury under George Washington and John Adams, and one of the signers of the Declaration of Independence. George Gibbs' father—the youngest child of George Gibbs III—was Francis Sarason Gibbs, who spent his earlier adult years in Canton and Shanghai, China. He was engaged for the greater part of his life in the grain exporting business. His later years were spent in New York City and Nyack, N. Y.

In his book entitled, "The Gibbs Family of Rhode Island," Mr. Gibbs (the subject of this memoir) says of himself:

> "Throughout a long and active life I have been fortunate in having good friends and owe much to the careful bringing up by a good mother who taught me the importance of faithfulness in the performance of responsibilities. Inherited qualities determined the direction of my career in life."

---

[1] Memoir prepared by E. Rowland Hill, M. Am. Soc. C. E.

Several generations of the Gibbs family had been fond of the natural sciences, and these leanings took the form of a fondness for engineering in Mr. Gibbs' case. He was graduated in 1882 from Stevens Institute of Technology, at Hoboken, N. J., one of the earliest engineering colleges in the country. He was among the first of its graduates. The first work he was able to secure after graduation was as laboratory assistant for Thomas A. Edison, who presently appointed him superintendent of meters in the world's first central power station, Pearl Street, New York. Later he became chief chemist of the Oxford Nickel and Copper Company at Bergen Point, N. J.

George Gibbs' railroad career began in 1885 when, through Roswell Miller, an intimate friend of his father's, he was offered a position with the Chicago, Milwaukee and St. Paul Railway Company to organize and take charge of a new department—that of physical and chemical tests of materials. He soon advanced to the position of mechanical engineer and was placed in charge of all machinery, locomotive, and car designing, in addition to his duties as chief of the Department of Tests. In this capacity he became particularly interested in advancing safety in railroad operation. To this end he devised, after some experimentation, a practical steam-heating system for trains and this, when put into effect, made the St. Paul Road a pioneer in safer and better train heating. For more complete protection of trains from fire, after elimination of the coal stove, it became necessary to abolish the use of the kerosene lamps for lighting cars. To this end Mr. Gibbs designed a system of electric lighting for heavy through trains that proved a great success and came into extensive use on the St. Paul Road. During these years he was active in conducting tests of brakes for freight trains, improving signaling systems, etc., and he patented numerous inventions, notably in the direction of safety appliances. While with the railroad Mr. Gibbs, with his brother, Lucius, organized the Gibbs Electric Company of which he was president. This company devised and manufactured a practical line of electric motors for general factory use.

During these activities in the West, George Gibbs became acquainted with two very prominent men in industry, the late George Westinghouse, M. Am. Soc. C. E., famous inventor of the air-brake and manufacturer of steam and electric machinery and railway signaling equipment, and Samuel M. Vauclain, M. Am. Soc. C. E., of the Baldwin Locomotive Works, Philadelphia, Pa. These men had come to the conclusion that heavy electric traction might soon be a possibility and might become of great importance in their manufacturing fields. At Mr. Vauclain's suggestion they accordingly arranged with Mr. Gibbs to become associated with them in the development of electric locomotives, and to make this arrangement possible Mr. Westinghouse's company purchased the Gibbs Electric Company. Mr. Gibbs established residence in Philadelphia in this new and dual capacity and thus became more intimately associated with George Westinghouse. For the Westinghouse and Baldwin companies Mr. Gibbs developed the low-built type of electric locomotive for restricted headroom service in mines, which has become standard in America.

While thus engaged Mr. Gibbs was asked also to represent the Westinghouse interests abroad in connection with heavy electric traction, and during the next few years (1900–1902) he was chief engineer of the Westinghouse Companies in England and on the Continent. He made many trips to Europe in connection with electrification projects for the Metropolitan Railway (Inner Circle) in London, England; Mersey Railway in Liverpool, England; and certain of the tube railways in London; and also was consultant for the Paris Underground Railway and other projects on the Continent.

The period 1902 to 1906 was one of great development in railroad terminal building and heavy electric traction in the vicinity of New York City, and during this period George Gibbs was first vice-president of Westinghouse, Church, Kerr and Company, then an outstanding firm of engineers. This position enabled him to take on independent consulting work, and he served as a member of the Electric Traction Commission of the New York Central Railroad Company in connection with its new Grand Central Terminal; was consulting engineer for the Rapid Transit Subway Construction Company, which constructed the first New York City subway; designed and installed the electric traction system and equipment for the Long Island Railroad Company; and became consulting engineer for the Pennsylvania Railroad Company. In 1905 George Gibbs was appointed chief engineer of Electric Traction and Station Construction for the Pennsylvania Railroad's New York Tunnel and Terminal Line then being constructed and a member of the Board of Engineers responsible for this entire improvement. This service continued until the completion of the station and terminal lines in 1910–1911.

Mr. Gibbs' interests in promoting the maximum of safety on railroads led him, in connection with his work for the New York subway, to design and patent the first all-steel passenger car ever put into practical use on a railway, a revolutionary idea at the time but one which he regarded as essential for high-speed tunnel and underground operation. The Subway Company adopted his plans and had built initially 300 cars of this new type. The Long Island Railroad Company also adopted it for its new electric lines in Brooklyn, N. Y., as did the New York Central Railroad Company for its Park Avenue tunnel line. The Pennsylvania Railroad Company, in view of the success of the new car, determined to bar all wooden cars from its New York tunnels and station, a far-reaching decision which meant the adoption of the steel car everywhere on its system and ultimately on all American railways.

To continue in the electric traction field after the completion of the Pennsylvania Railroad Terminal, early in 1912 George Gibbs and the writer, who had been closely associated on heavy electric traction development and related projects since 1898, formed a partnership for conducting a general engineering practice. This firm, later incorporated, has been responsible for the design and execution of much of the important electrification work on American railways. Such installations have included the electrification of the Norfolk and Western Railway and the Virginian Railway, mountain grade heavy coal and freight haulage lines—50 and 130 miles long, respectively; extensive additions and changes to electrification equipment and power plants of the New York, New Haven and Hartford Railroad and the New York Connecting Railroad and Long Island Railroad companies' freight line operated by the New Haven

(Hell Gate Bridge Line); the Chicago Suburban electrification of the Illinois Central Railroad; and the suburban lines of the Pennsylvania Railroad in the vicinity of Philadelphia, and more recently the electrification of all through passenger and freight services of the Pennsylvania Railroad between New York and Washington, D. C., and to Harrisburg, Pa. The Pennsylvania lines thus electrified comprise 670 miles of route and a power load of 200,000 kw, and involved a cost of more than $150,000,000; the line operates 260 electric locomotives and 500 multiple unit cars. There also have been consulting or designing engagements for numerous industries, public utility companies, city transit lines, and public service commissions, including the Public Service Commission of New York in connection with the dual subway transit system.

During the World War Mr. Gibbs was a member of the United States Government Advisory Commission of Railway Experts to Russia, and spent seven months on behalf of Russia and the Allies on the reorganization of Russian transportation facilities. This involved the examination in detail of the 30,000 miles of railways in European and Asiatic Russia. Later Mr. Gibbs advised the Ministry of Transport of the British government on electrification projects for lines radiating from the City of London.

In addition to being a Past-Director of the Society, which awarded him the Norman Medal in 1912 and the Wellington Medal in 1931, Mr. Gibbs was a member of the British Institution of Civil Engineers; member and past-president of the American Institute of Consulting Engineers; Fellow of the American Institute of Electrical Engineers; a member of the American Society of Mechanical Engineers, the American Railway Engineering Association, American Railroad Association, and American Mathematical Society. He was the author over a period of many years of numerous technical papers published in the *Proceedings* of the societies and the press.

In the non-technical societies Mr. Gibbs' membership included Descendants of the Signers of the Declaration of Independence (great-great-grandson of Oliver Wolcott), Society of the Cincinnati, and numerous charitable and educational institutions. He was a member of the Board of Trustees of Presbyterian Hospital (Columbia University Medical Center) and vice-president and chairman of the Executive Committee of the Woman's Hospital, New York.

Mr. Gibbs was a Life Trustee of Stevens Institute of Technology, his alma mater, which in 1930 conferred upon him the honorary degree of Doctor of Engineering, with the citation:

> "International authority on the electrification of railways; introducer of the all-steel car; during the Great War a member of the United States Railway Commission to Russia; for many years designer and constructor of equipment mainly electrical, for the intricate surface, underground and underwater arteries of travel that serve and control the concentrations of peoples and industries in the centers of population of this and other countries; human servant of the public through his effective participation in the direction of two great hospitals; a son of this college who has brought to it honor and affectionate service."

Mr. Gibbs' clubs included: The Century Association, New York Union, University, Brook and Downtown, New York, Rittenhouse, Philadelphia, South

Side Sportsmen's (Oakdale), and Long Island and Cascapedia Salmon Club, Canada.

Throughout his career Mr. Gibbs exhibited the desire and determination to excel in the quality of the things he created and in this he possessed masterful skill, balanced and farsighted judgment, and persistence in carrying through to ultimate success the thing he believed to be the best in any situation. There was courtesy, charm, and dignity in his associations with others, both in professional and personal relationships; he had a fondness for art and music, being a regular attendant at the opera and a frequent visitor to the centers of culture abroad; he possessed a keen sense of humor and enjoyed, for recreation and change, nature's open spaces of forest, stream, and sea.

Mr. Gibbs was not married; he was devoted to his brother and sisters and took an unusual interest in their children.

Mr. Gibbs was elected a Member of the American Society of Civil Engineers on March 6, 1895.

RALPH EDWARD GOODWIN, M. Am. Soc. C. E.[1]

DIED DECEMBER 16, 1939

Ralph Edward Goodwin was born in East Hartford, Conn., on September 26, 1886. He was a descendant of Ozias Goodwin who went to Boston, Mass., from England in 1632, and through the wilderness to Hartford with Thomas Hooker's first party in 1635. John Goodwin, in the direct line of descent, went to East Hartford in 1697 and acquired the land on which Ralph Edward Goodwin was born. Ralph and two sisters were the children of Joseph Olcott Goodwin and Harriet Jane (Spencer) Goodwin. The father was town clerk of East Hartford for more than 48 years.

As a boy, Ralph Goodwin attended Miss Loomis' private school and the Hartford Public High School. He received his Bachelor of Arts degree from Yale University at New Haven, Conn., in 1908, and then entered Sheffield Scientific School, from which he was graduated with a Bachelor of Philosophy degree in 1909. He was an excellent student, and at Yale was honored by election to the Phi Beta Kappa and Sigma Xi fraternities.

Mr. Goodwin's first professional work was as a rodman with a United States Government Survey party along the Connecticut River during the summer of 1909 but in the fall he returned to Sheffield Scientific School as assistant in civil engineering.

He taught several civil engineering courses at Sheffield during the next two years, and in turn, as he said, "these years as assistant in civil engineering taught me to work mercilessly without thought of reward and also put me in line for the degree of Civil Engineer, which I much coveted." In June, 1911, at the end of this period of training, he joined the New York Central and Hartford Railroad Company as a rodman, and in one month became a transitman on a variety of surveying and mapping work. He felt that his pay was not sufficient to permit him to buy life insurance and, as he expected to be killed on the tracks before he could get another increase in salary, he left the company in March, 1912. From that date through May, 1912, he was temporary assistant engineer with the New York Board of Water Supply on the New York City pressure tunnel. He gave lines and grades, kept progress records, and had supervision over dynamite. On this job he gathered material to complete his graduate thesis, and he obtained the degree of Civil Engineer from Yale University in 1912.

---

[1] Memoir prepared by William Allan, Assoc. M. Am. Soc. C. E.

While serving as assistant at Sheffield Scientific School Mr. Goodwin formed his decision to become a teacher of civil engineering, and true to this objective, in June, 1912, he accepted the position of assistant in civil engineering at Columbia University, New York, N. Y., and began his work by teaching at Columbia's Summer Surveying Camp. Throughout the school year in his work designing and detailing experimental columns for the testing laboratory, Mr. Goodwin furthered his great interest in column theory and design and subsequently prepared a brochure on that subject. For the summer of 1913 he returned to Yale University as instructor in charge of topographic and mine claim surveys and office work for mining engineering students.

Thereafter Mr. Goodwin turned again to professional work for a period of nine years. For the first three and a half years he was a junior engineer in the Division of Materials Inspection of the New York State Public Service Commission in New York City. He had charge of the inspection of concrete aggregate and of the physical testing laboratory which he equipped for testing and inspecting concrete and aggregate for subway and elevated railroad construction in New York City. For one year following this Mr. Goodwin was an estimator for the Chile Exploration Company of New York City and prepared quantity and cost estimates and wrote specifications for construction materials for the living accommodations and public works of a South American mining plant. From April, 1918, until May, 1922, he served with the United States Shipping Board in the Hull and Machinery Departments as an inspector of construction and repairs on vessels.

In November, 1922, he returned to teaching as instructor in drafting and mathematics in the Veterans' Vocational Training School at the College of the City of New York; and in February, 1923, he joined the staff of the School of Technology of the City College. He rose from the rank of instructor to that of associate professor of civil engineering. In that period Professor Goodwin taught many of the courses in the civil engineering curriculum, and for years directed the Summer Surveying Camp at Van Cortlandt Park and all course work in strength of materials. At the time of his death he was secretary of the School of Technology Faculty and also of The City College Faculty Conference, a member of the Committee on Appointments of the Civil Engineering Department, and program and curriculum adviser to civil engineering students. Of the countless other tasks which he did without flourish or note, many will never be known.

He was a truly competent, scholarly man, whose active and productive work in the School of Technology helped to raise its level of achievement and influence to a high position. He wrote a text book entitled "Advanced Strength of Materials and Structural Design"; manuals for Materials Testing Laboratory, and for First and Second Summer Camp Surveying; and brochures on least squares and on column theory and design. Throughout his professional life he contributed many papers and discussions on technical subjects to civil engineering periodicals.

Within the range of his specialty, Professor Goodwin was a master in a creative way and, along with his strength in science and its applications, he was also a master of that rare art of conveying knowledge in a form and manner suited to the students' powers of assimilation. He further possessed wide general knowledge and interest in all human activities, particularly those of his students.

Special distinction came to Professor Goodwin through the trust reposed in his integrity and through his willingness to be of service. He won the confidence and esteem of the entire school and of its graduates, thereby gaining a reputation closely interwoven with the lives and experiences of those who knew him. He was quiet and unassuming in manner, but independent in thought; and his capacity for calm, unbiased judgment caused his advice to be much sought after. These qualities, together with his sincere and friendly attitude toward all, won him great affection and respect.

In 1912 Mr. Goodwin was married to Gilberta Hopkins Daniels, daughter of Prof. Archibald L. Daniels of the University of Vermont, Burlington, Vt. He is survived by his widow; their son, Robert Daniels; and a sister, Jessie (Mrs. H. A. Preston).

No finer tribute could be expressed in Professor Goodwin's memory than that voiced by several of his friends on learning of his death: "He was the best one among us; surely if all men were as tolerant, as kind and as truly able as he was, the way to Utopia might be found."

Professor Goodwin was elected a Junior of the American Society of Civil Engineers on October 1, 1912; an Associate Member on April 16, 1918; and a Member on June 10, 1935.

ROY COTSWORTH GOWDY, M. Am. Soc. C. E.[1]

DIED JUNE 10, 1939

As evidence of how a young man without the opportunity of a college education can, by energy and ambition, qualify himself as an engineer, Mr. Gowdy's early experiences are given in considerable detail.

Roy Cotsworth Gowdy was born in Washington, Iowa, on September 3, 1878. He was a son of Leander Harper Gowdy, who was born in Monmouth,

---

[1] Memoir prepared by Herbert S. Crocker, Past-President and Hon. M. Am. Soc. C. E.

Ill., and Annie Laurie (Reid) Gowdy, who was born in College Springs, Iowa. He was of Scotch descent on his father's side and of English descent on his mother's side. When he was four years of age his family moved to Colorado Springs, Colo., where he received his early education in public schools, graduating from the high school in 1896. He then attended Colorado College, at Colorado Springs, for one year, but discontinued his courses because of ill health. Thirty-nine years later, in 1935, upon presentation of a thesis, he received the degree of Civil Engineer from the University of Colorado, at Boulder, Colo.

Like most embryo engineers, Mr. Gowdy seems to have been an opportunist. His early experience was as stakeman, axman, and rodman, performed under the direction of H. I. Reid and other engineers and surveyors in the area contiguous to Colorado Springs. In 1899 he was employed by the Colorado Springs and Cripple Creek District Railway Company as calculator with a locating party making surveys for a standard steam railway between those points. Subsequently he became a rodman and instrumentman on the construction of the line. His connection with this company continued intermittently until the fall of 1902. At the same time he was in private practice and doing minor engineering work for various engineers. He was then engaged in similar capacities by the Denver, Northwestern, and Pacific Railway Company (Moffat line) during its survey and construction. This engagement was terminated in 1904.

Mr. Gowdy then returned to the Colorado Springs and Cripple Creek District Railway Company where he was employed as draftsman and assistant engineer of maintenance of way. He remained with that company until the summer of 1905 when it was purchased by the Colorado and Southern Railway Company and its engineering department was discontinued. This work was followed by employment by E. C. van Diest in Colorado Springs as draftsman and clerk.

After his preliminary training in subordinate positions, which had been supplemented by outside reading and study, Mr. Gowdy attained his first important engagement on April 21, 1906, when he was employed by the Ft. Worth and Denver City Railway Company, an affiliate of the Colorado and Southern Railway Company, as engineer in charge of the design and construction of a freight terminal which it was building in Fort Worth, Tex. This work was important in that it involved responsible charge in the field of those many details which must be carefully and progressively worked out in construction of that kind. It also involved considerable designing, under the general direction of the late Herbert W. Cowan,[3] M. Am. Soc. C. E., who was at that time chief engineer of the Colorado and Southern Railway Company. To be associated with Mr. Cowan was an honor as well as a privilege.

In November, 1906, Mr. Gowdy was appointed resident engineer of the Fort Worth and Denver City Railway Company, in which capacity he had charge of all its engineering work, including the completion of its terminal work at Fort Worth. This work also was done under the general direction of Mr. Cowan.

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXX, December, 1916, p. 2124.

In 1908 he was appointed chief engineer of that company and of the Wichita Valley Lines. In this capacity he had charge of all engineering matters for both companies. During this period, and up to 1918, the work which Mr. Gowdy performed was largely the general routine of railway maintenance of track and reconstruction of bridges and other structures, among which were depots and incidental buildings. Following a fire at Childress, Tex., Mr. Gowdy had charge of the construction of a new plant, including locomotive and car repair shops, roundhouse, and other facilities.

In 1918 the United States Government took over the operation of all the railway lines in this country as a war measure. Following this change of administration Mr. Gowdy served for a few months as division engineer under the late Frank Merritt of Galveston, Tex., for a group of lines in northern Texas. However, in August of that year he resigned from that position to become corporate chief engineer of the Colorado and Southern Lines, which included the Colorado and Southern Railway Company, Fort Worth and Denver City Railway Company, Wichita Valley Lines, and their subsidiaries, with headquarters in Denver, Colo. This connection continued until the railway properties were returned to their owners by the government on February 29, 1920, after which Mr. Gowdy was chief engineer of the Colorado and Southern Railway lines, including the Fort Worth and Denver City Railway, with offices in Denver and Fort Worth, until his death.

In 1909, by purchase of a majority of its stock, the Chicago, Burlington and Quincy Railroad Company acquired the Colorado and Southern Railway and from that time forward gradually assumed direction of it and its subsidiaries. However, this did not affect Mr. Gowdy's authority except that he was in frequent consultation with the officers of the Burlington, and conformed to its general policies and budgetary control.

Mr. Gowdy's duties were largely in accordance with the general routine of railroad administration. They included improvements in alinement, renewal of bridges, the construction of the Canadian River bridge in Texas, and the preparation of necessary data, with their presentation as a witness before members and examiners of the Interstate Commerce Commission in cases seeking to procure the approval of the Commission of proposed new lines or the abandonment of existing standard-gage and narrow-gage lines.

Some important exceptions to the routine are certain major constructions which drew upon his powers of judgment in location and designing, and ability in the letting and handling of large contracts. These are probably described better in his own words:

> "During the earlier years of their existence, the Fort Worth & Denver City Railway Co. and the Wichita Valley Lines enjoyed almost a complete monopoly of the territories in which they operated. This condition was due in part to the large areas of the northern part of Texas which had never been developed agriculturally, and in part to the tremendous natural

barrier known as the Cap Rock, extending from the northern part of the State far down towards the Colorado River, and separating the lower Plains country from the drainages of the Red and the Brazos Rivers. Overcoming this barrier presented serious difficulties even for highways, and more serious ones for the location and construction of railroad lines. Opening of the South Plains territory to agriculture brought with it the construction of railway lines from the north and the south, which seriously menaced the tonnage handled heretofore by the Fort Worth & Denver City and Wichita Valley Lines, and this fact, together with a desire to enter a new and growing country, made the extension of those lines desirable and necessary. For several years I worked with the executive and traffic officers of the companies in making traffic and other surveys of the large area lying between the Fort Worth & Denver City Railway Company's main line and the line between the States of Texas and New Mexico. My particular portion of this work had to do with the possibilities of procuring feasible routes from the main line to the foot of the Cap Rock and surmounting the Cap Rock, and their cost, but I also helped in the traffic, financial, and economic studies which were made.

"At about the same time the South Plains country came into prominence agriculturally, the vast territory in the Pan Handle of Texas north of the Canadian River began to open up and was followed by the development of what later became known as the Amarillo oil fields. These developments and the desire of my companies to procure an outlet to the northeast resulted in extensive surveys being made, under my supervision, into Oklahoma, the southern part of Kansas and the southeastern part of Colorado.

"When it was finally decided to build westerly from some point on the main line of the Fort Worth & Denver City into the lower Plains country, I was instructed to ascertain the most feasible and economical route, and to locate and construct a line capable of handling cattle, grain, cotton, and other agricultural products in the most economical and expeditious manner. The Cap Rock, mention of which has been made above, presented the most serious difficulty in the location of a line, and made necessary a detailed investigation of a very large area of country, and the running of many preliminary and exploratory lines before a final route was selected. At one time four locating parties were engaged in this work, and about 1200 miles of preliminary lines were run before the final location of the 65 miles from the main line to the top of the Cap Rock was made.

"The construction of the more than 200 miles of track westerly from the main line of the Fort Worth & Denver City involved some exceedingly heavy work, and unusual construction methods were found necessary. The broken and rugged character of the country in the area immediately below the Cap Rock made it necessary to drive several tunnels from 200 ft. to a little less than 700 ft. in length, erect long and high trestle bridges, and move a very large amount of earth and rock. The construction of this line was unique, in that the engineering forces located, constructed, and turned over to the Operating Department a working machine complete in every detail. All station, roadway, and other buildings were entirely completed, depots contained all furniture, stationery, and other supplies necessary, section gangs had been equipped with tools and were at work, and shop and engine facilities were in operation when the line was released by the engineering forces. This project was also unique in that the line was operated for freight service for several months by the engineering forces under my jurisdiction before it was turned over to the Operating

Department. Operating results obtained since the line was opened for service indicate that its construction was justified and that no serious errors in its location, grades, and general construction were made.

"Surveys for lines running northerly and northwestly from the main line of the Fort Worth & Denver City into Oklahoma and Kansas were carried on at the same time the lines were run into the South Plains country. About the time the new line into the South Plains was placed in operation, the Amarillo oil and gas field became active, and surveys for a line into that field were undertaken and a line was located from Childress, a point on the main line of the Fort Worth & Denver City Company, northerly across the Prairie Dog Town and the Salt Forks of the Red River to the North Fork of the Red River, and thence northerly and westerly up the North Fork to the town of Pampa. Portions of this line were in rough country, but no unusual location or construction difficulties were encountered, except that the river crossing made long bridges necessary. The unusual feature of its construction was the time in which the work was done. With the cooperation of the contractors, the Hamilton & Gleason Company and Roberts Brothers, in a period of less than ten months, more than 2,000,000 cubic yards of earth excavation and embankment and 1,400,000 cubic yards of loose and solid rock were moved. In the same period, and while grading was under way, that firm drove approximately 160,000 lin. ft. of creosoted piling, varying in length from 12 ft. to 100 ft., and placed more than 2100 MBM of creosoted lumber. The track on this line was laid by company forces and was kept so close behind the grading that several times grading would be completed by night shifts, and track forces would start laying track the next morning."

Mr. Gowdy was a man of kindly and generous disposition, loyal to his friends, and of high character. In his business dealings he was conscientious in all things and had the faculty of being able to see clearly both sides of a contention. His decisions were, therefore, wise and fair. He enjoyed a circle of many friends who were attracted to him by his resourceful mind and sympathetic understanding. He was an upright man.

Mr. Gowdy was a Master Mason and a Knight Templar. At the time of his death he was a member of the Plymouth Congregational Church, the Denver Athletic Club, and the Lakewood Country Club.

He had a keen interest in professional matters outside of his business. He was president of the Colorado Engineering Council for two years, as well as its delegate to the American Engineering Council for a corresponding length of time. He was also a member of the American Railway Engineering Association and of the Colorado Society of Engineers. In 1918 he served as President of the Texas Section of the American Society of Civil Engineers and in 1927 as President of the Colorado Section.

He had one brother and three sisters; two of the latter survive him. He was married to Emma Lee Maiden of Colorado Springs on June 27, 1905, who, with a son, Joseph Scott Gowdy, Jun. Am. Soc. C. E., born June 5, 1907, survives him.

Mr. Gowdy was elected an Associate Member of the American Society of Civil Engineers on October 31, 1911, and a Member on January 18, 1916. He served as Director in 1930–1931 and as Vice-President in 1937–1938.

EDWARD FRANCIS HAAS, M. Am. Soc. C. E.[1]

DIED APRIL 13, 1939

Edward Francis Haas was born on August 28, 1870, in Stockton, Calif., the son of Charles Haas and Charlotte (Merk) Haas, who were among the early California pioneer families.

Mr. Haas attended the public schools in Stockton, and was graduated from Stockton High School in 1888. He attended the University of California, at Berkeley, Calif., where in 1892 he was graduated with high honors, receiving the degree of Bachelor of Science in Civil Engineering.

From 1892 to 1893 he was instructor in Civil Engineering at the University of California, after which he attended the Columbia School of Mines of Columbia University, New York, N. Y., receiving his Civil Engineer Degree in 1894. Returning from Columbia University to Stockton, he worked in the City Engineer's Office for one year. Thereafter he was in private practice in the City of Stockton until 1897.

Always deeply interested in the problem of reclaiming the fertile delta lands of the San Joaquin and Sacramento rivers, Mr. Haas soon became engineer in charge of the reclamation of about 20,000 acres of swamp land in these delta regions. He built about twenty miles of levees, three miles of main canal, and large pumping plants for drainage. During this time he was sent to Alaska to make an engineering report for a large mining project which included difficult transportation problems.

In 1898 Mr. Haas took up residence in San Francisco, Calif., where he became affiliated with the City Engineer's Office in preliminary studies for an adequate sewer system.

He was associated with the late Carl E. Grunsky,[2] Past-President, Am. Soc. C. E., from 1899 to 1900 in the design and construction of a sewage system for the City of Belvedere, Calif. Mr. Haas was the engineer in charge of construction.

In 1900 he was engaged, by the Board of Engineers of the City of San Francisco, to design a comprehensive and modern sewage system for the City of San Francisco at an estimated cost of $4,600,000. Mr. Haas was in responsible charge of design for various sections of the system throughout the city. Following this he became assistant engineer in the newly created Board of Public Works, with Mr. Grunsky as city engineer of the City of San Francisco.

In 1901 he entered into partnership with John W. Ferris. The firm, known as Ferris and Haas, engaged in the prosecution of various dredging and reclamation contracts, which often included the necessary engineering. In the winter of 1901–1902 the partnership received from the United States Government the original dredging contract to deepen Pearl Harbor at Honolulu, Hawaii. Mr. Haas, as managing partner, was in Honolulu in charge of the work.

---

[1] Memoir prepared by F. C. Herrmann and Thomas H. Means, Members, Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1591.

During this partnership Mr. Haas maintained independently his private practice of engineering, and was associated with the late Marsden Manson,[8] M. Am. Soc. C. E., in the design and construction of the sewer system of the City of Marysville, Calif.; as associate engineer on design and enlargement of the Placerville (Calif.) Water Works System; as engineer in charge of dredging of the ship channel to Mare Island Navy Yard; and as engineer and manager of the West Coast Canal Company which dredged the navigation channel for the United States Government in San Pablo Bay.

In 1906 Mr. Haas organized the Union Dredging Company, and in 1909 the Caledonia Dredging Company. He acted as president of both of these companies.

The work under the partnership of Ferris and Haas, and as continued by the Union Dredging Company and the Caledonia Dredging Company, consisted largely of river rectification and the work of various reclamation districts and so-called islands of the Sacramento and San Joaquin Delta, as well as marginal marsh lands of San Francisco Bay. Large sums of money were spent on these projects which added many thousands of acres of very fertile land and great wealth to the State of California. Because large portions of these projects consisted of " peat lands," Mr. Haas had to solve many difficult problems in the construction of levees, structures, and canals. By reason of these experiences, Mr. Haas was consulted about the design and construction of the railroad embankment across the San Joaquin River delta lands for the San Joaquin Valley Railroad Company, later the Atchison, Topeka and Santa Fe Railway Company.

Practically all of this work was done with floating dredgers, and Mr. Haas, keenly interested in the improvement of dredging equipment, participated in designing and developing the long-boom clamshell dredger in the Sacramento and San Joaquin regions.

In 1919 Mr. Haas, turning his attention to dry land excavation, formed a partnership with Frank Doughty, Assoc. M. Am. Soc. C. E., known as Haas and Doughty. In 1927 this partnership was enlarged to include Arthur Jones, the firm's name changing to Haas, Doughty and Jones. This partnership continued until Mr. Haas passed away.

Mr. Haas was the dominant figure in these partnerships, which were responsible for important construction work in several of the western states. For the United States Bureau of Reclamation, they constructed the main canals and appurtenant structures on the Minidoka and Boise projects in the State of Idaho; the Yakima Project in the State of Washington; the Vale Project in the State of Oregon; and the Contra Costa Canal of the Central Valley Project in the State of California. In Nebraska they participated in the construction of main canals and appurtenant structures for the Loup River Public Power District, and for the Central Nebraska Public Power and Irrigation District.

---

[8] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1554.

In addition to the foregoing, in California this firm constructed many miles of large levees of the Sacramento Flood Control Project on rivers and by-passes, as well as levees, irrigation, and drainage canals for many of the reclamation and irrigation districts in that state.

With his continued interest in the efficiency of earth-moving equipment, Mr. Haas, in conjunction with the Stockton Iron Works, developed the excavator with caterpillar treads. This was the forerunner of modern dragline equipment.

The success of these organizations which he dominated was due very largely to the exceptional ability of Mr. Haas to organize and develop a given task or project. This led to the concentration of his energies on contracting work, which continued in the foreground of his activities throughout his life. However he was always deeply interested in all engineering matters, as well as the welfare of the engineer.

Concurrently with engineering and contracting, Mr. Haas became interested in various types of business, outstanding among them being the Snelling Gold Dredging Company of California, of which he was vice-president. The organization and success of this company, like his many interests, was due largely to his ability as an engineer and business executive. This was true also in the organization of the Vermillion Natural Gas Company, later known as the Central Natural Gas Company of South Dakota, of which he was Chairman of the Board.

Aside from his engineering and business activities, Mr. Haas was continuously active as an Alumnus of the University of California and of Sigma Chi fraternity. He was also trustee of the First Presbyterian Church of San Francisco, and for many years was a member of the San Francisco Golf Club, the Commonwealth Club of San Francisco, The San Francisco Chamber of Commerce, Engineers Club of San Francisco, The Pacific Union Club of San Francisco, the Menlo Country Club, and the University Club of San Francisco, serving as president of the latter two clubs for two terms. For many years he was also a member of the Stockton Golf and Country Club, and the Yosemite Club of Stockton.

During the 1920's, Mr. Haas was appointed by the United States Army as engineer in a civilian group to survey the facilities of the Ninth Corps Area, in connection with the National Defense Program. He was charged with the gathering and correlating of various data relative to transportation equipment, water, and fuel supplies, etc., and performed this service in a meritorious manner as gratuitous and patriotic service to the public, and his work was highly commended by the Army officials.

Although he was a stern taskmaster to himself, Mr. Haas was sympathetic and generous to the appeal of others. Highly respected by all who came in contact with him in business, he was deeply loved by his friends and associates.

In June, 1931, Mr. Haas was delegated, together with Daniel W. Mead, Past-President and Hon. M. Am. Soc. C. E., to represent the Society at the Seventy-Fifth Anniversary of the existence of the *Verein Deutscher Ingenieure,* held at Cologne, Germany.

Mr. Haas is survived by his widow, Mabel Thompson Haas, one son, Edward Thompson Haas, one daughter, Alice Haas (Mrs. Frank N. Conner), and two grandchildren, Edward Jewett Conner and Syida Geraldine Haas.

Mr. Haas was elected a Junior of the American Society of Civil Engineers on February 6, 1894; an Associate Member on September 5, 1900; a Member on February 6, 1906, and a Life Member in 1935.

EPHRAIM HARRINGTON, M. Am. Soc. C. E.[1]

DIED JULY 20, 1939

Ephraim Harrington was born in Belmont, Mass., on December 2, 1861. He received his early education in the public schools of Roxbury, Mass. For a short time he attended the School of Mechanic Arts of the Massachusetts Institute of Technology, at Boston, Mass., in the class of 1879, but he did not graduate with his class.

He followed civil engineering work all of his life, starting with the City of Boston in 1877 in the Surveyors Department where he worked two years. Later he transferred to the Engineering Department of the City. From 1883 to 1885 he was transitman and inspector for the Boston, Hoosac and Western Railroad Company. From 1887 to 1888 he was transitman in charge of the work on the reconstruction of roads and bridges for the Toledo, St. Louis and Kansas City Railroad Company.

His most important work was begun in 1888 when he was employed by the Engineering Department of the West End Street Railway Company (later a part of the Boston Elevated Railway). This work continued for five years. In 1893 he and the late Gilbert Hodges formed the engineering firm of Hodges and Harrington, Civil Engineers, with an office in Boston, practicing in steam railroad and electric railway construction and general engineering.

The firm of Hodges and Harrington was probably the most prosperous engineering firm in Boston at that time. It was very active in the rebuilding of old horse car lines to adapt them to electric car operation. As this was a new field there were few precedents.

Hodges and Harrington were the engineers for the majority of the interurban lines in Massachusetts, New Hampshire, Rhode Island, and a part of Vermont. This work included most of the 900 miles of the tracks comprising the Eastern Massachusetts Street Railway, later largely abandoned to make way for buses. The firm was dissolved in 1900 and Mr. Harrington practiced general engineering, especially the construction and layouts of street railways, a comparatively new field. In later years he confined himself to more general work, particularly after the various traction companies organized their own engineering departments.

---

[1] Memoir prepared by Frank B. Walker, M. Am. Soc. C. E. Mr. Walker died on June 3, 1940.

Mr. Harrington was an extremely reserved man and did not "mix" to a great degree with either his assistants or associates, presumably from shyness. His hobby was the Appalachian Mountain Club which he joined in 1892. His loyalty to the club remained to the end of his life. He was a leader of winter parties and organized the Snow Shoe Section for the purpose of encouraging snow shoeing as an aid to mountain climbing. He knew the fundamentals of equipment and gave much attention to its proper selection. In June, 1918, he published a code for signals in the magazine *Appalachia,* and later wrote a "Few Notes on the Uses of the Compass in the Woods" for the same magazine. He initiated the wood chopping enterprise and was one of the outstanding members of this famous mountain club.

Mr. Harrington outlived most of his associates. For many years he lived in West Roxbury, a part of Boston. He was a member of the West Roxbury Citizens Association, the Unitarian Club, the Unitarian Laymen League, and a Trustee of the First Parish for nearly forty years.

He was married to Lina Sophia Weld of Dedham, Mass., on October 10, 1894. He is survived by an older brother, David A. Harrington, a civil engineer of Norwell, Mass.; a sister, Susan T. French; a daughter, Ruth Weld Harrington; and a son, Davis Weld Harrington.

Mr. Harrington was elected a Member of the American Society of Civil Engineers on March 3, 1897.

PHILIP HART, M. Am. Soc. C. E.[1]

DIED NOVEMBER 29, 1938

Philip Hart was born in Portland, Ore., on June 8, 1887, the son of James Dixon Hart and Mary (Goodenough) Hart. The scion of a prominent Portland family, he had his preparatory education in the Portland Academy, graduating with the class of 1905. It was there that he formed friendships with James H. Polhemus, M. Am. Soc. C. E., general manager of the Port of Portland, and Ben S. Morrow, Assoc. M. Am. Soc. C. E., general manager of the water department of the City of Portland. These friendships ripened with the years, and continued with increasing mutual esteem until the day of Mr. Hart's death. Along with many other "Portlanders," Mr. Hart received his university education at the Massachusetts Institute of Technology, at Boston, Mass., graduating in 1910 as a mechanical engineer.

Mr. Hart early gave evidence of the original mind and dauntless spirit which were to be his key to success in later life, and the basis of his life's work. In 1912 he did some minor underwater foundation work at the plant of the St. Helens Lumber Company in St. Helens, Ore. He did his own diving, and all the difficult work with his own hands; perchance while doing work that had the ordinary run of workmen frightened, he conceived the idea of making a business out of work that was too difficult to attract the ordinary contractor, thus enhancing the profit possibilities by elimination of competition.

---

[1] Memoir prepared by F. W. Crocker, M. Am. Soc. C. E.

His first major business venture was in 1914, at the age of 27, in the firm of Sharp and Hart, dealers in transmission and conveying equipment in Portland. This did not provide full scope to Mr. Hart's energy and in 1915 he withdrew. This incident is mentioned to illustrate his daring spirit. In 1914 business in Portland was at the lowest ebb in history—you could hire the entire town for twenty-five cents an hour. Mr. Hart had accepted family responsibilities, and was having plenty of trouble getting on his feet, but he had to have his own business.

His next connection was with the Pacific Bridge Company, then engaged in the construction of the piers for the Interstate Bridge across the Columbia River between Portland, Ore., and Vancouver, Wash.; also upon the paving of a 10-mile section of the Columbia River Highway from Multnomah Falls, Ore., to the Multnomah County line and past the present site of the Bonneville Dam. The company, then under the presidency of the late Charles F. Swigert,[3] M. Am. Soc. C. E., had had an honorable history dating back to its founding in California by R. W. Gorrill in 1869. This is a long life for any construction company engaged in the hazardous undertakings that appealed to the Pacific Bridge Company. However, it had not had an unbroken line of successes; after a brief period of success a crushing setback would usually follow, and these setbacks would be more than any but the dauntless spirit of Mr. Swigert could endure.

The two aforementioned projects proved quite profitable, but the company was to run true to form and dissipate much of its hard won gains in an ill-advised venture in the East in 1916 where the existence of pre-war conditions made successful operations impossible. Mr. Hart would be the last to claim credit, but this reverse set him to thinking, and his function thenceforth was to build an organization for the Pacific Bridge Company that would render such setbacks impossible and that would enhance the company's successes and allow it to attain its so well-deserved place in the construction industry. The realization of this ambition was to take some time, but the leaven was working, and, knowing Mr. Hart, it was only a question of how many years would elapse until he had just the kind of organization he wanted, and the company could make profits with some hope of keeping them.

Then came the war. Mr. Hart enlisted in the Corps of Engineers; served at Ft. Humphreys, Virginia; received a commission as Captain on November 7, 1918; and was mustered out December 31, 1918.

After the war came a vast amount of highway work in Washington and Oregon, at first quite profitable; and of this work the Pacific Bridge Company received its share. Such work offered little opportunity for personal ingenuity, however, and, as usual in state highway work, there was a constant stream of new bidders coming to the front attracted by the frequent public lettings. This had a demoralizing effect on prices and profits, and toward the end of 1921 Mr. Hart was willing to admit that highway building was not the right business for the Pacific Bridge Company. He was as anxious to drop it as he had been to get out of the transmission machinery business six years before. During this period he had built as his own personal venture the Oswego Creek arch, seven miles south of Portland on the Pacific Highway.

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1657.

He was not to languish for long. In the spring of 1922 the lift bridge across the Cowlitz River in the City of Kelso, Wash., was built. Then a bascule bridge across the Lewis and Clark River about seven miles from Astoria, Ore., was constructed. There was an unusual foundation accident on this structure for which Mr. Hart's company had to pay in large part, but for which they were not to blame. However, they were on their way upward then and such setbacks were " all in the day's work."

Enough progress had been made in the position of the Pacific Bridge Company that Mr. Swigert decided to reorganize the company in August, 1919, and give the younger element recognition. At that time Mr. Hart became a member of the company and its treasurer. He had started as assistant engineer and had been advanced to engineer in November, 1917. In 1928 he became vice-president of the company, and in 1935 succeeded Mr. Swigert as president.

In the fall of 1922 the City of Portland issued bonds for the construction of the Burnside and Ross Island bridges across the Willamette River, and in the fall of 1923, under Hedrick and Kremers as consulting engineers, called for bids on the foundation of the Ross Island Bridge. The late Ira G. Hedrick,[3] M. Am. Soc. C. E., had been brought up on Midwest pier construction methods, and insisted on building this bridge on pneumatic caissons. The Pacific Bridge Company had developed quite a technique for building open caisson pile foundations and this had become standard practice in the Northwest. They had all the equipment for building open foundations cheaply and desired to qualify, if possible, as bidders on the pneumatic foundations at Ross Island. Mr. Hart, with the assistance of John Lyle Harrington, Ernest Emanuel Howard, Members, Am. Soc. C. E., and the late Louis Russell Ash, consulting engineers of Kansas City, Mo., prepared a plan for doing all the excavating work in the open, then sinking the pneumatic deck in the hole, sealing it around the outside, weighting it on top, applying the locks, blowing out the air, and allowing the engineers to examine the bottom. Thereafter the work was continued as for a pneumatic foundation. On this the Pacific Bridge Company made the low bid for the work and was promptly rejected as not offering a pneumatic caisson. However, Mr. Hedrick's eyes had been opened as to the possibilities of the open caisson and he proceeded to make new plans for both bridges.

The next letting came in the spring of 1924 and, after considerable controversy due to unscrupulous competition, the contract for the Burnside Bridge was awarded to the Pacific Bridge Company. This work, after three bad setbacks in the spring of 1935, proved quite successful and at this time Mr. Hart may be said to have realized his ambition for the success of the Pacific Bridge Company.

After that came in rapid succession the following contracts:

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 1932.

1925—Foundations for Ross Island Bridge, Portland.
1926—Bridge over Cowlitz River for the City of Longview, Wash.
Harbor wall along the Willamette River in Portland (the Laurgaard plan).
1927—Subaqueous pipe crossings for the Mokelumne pipe line under the three branches of the San Joaquin River (in connection with J. F. Shea Company).
1928—Foundations for Longview Bridge across the Columbia River.
1929—Foundations for St. Johns Bridge across the Willamette River in Portland.
Foundations for Aurora Avenue Bridge across Lake Union, Seattle, Wash.
Submerged pipe line for the Standard Oil Company of California in the Pacific Ocean at Estero Bay, California.
1930—Pipe lines and submerged pipe lines for Everett, Wash.
Headworks and pipe line for Anacortes Water Supply, Anacortes, Wash.
1931—Submerged pipe lines across San Joaquin River on the Hetch Hetchy project.

In 1931 the Pacific Bridge Company became a constituent company of Six Companies, Incorporated, on the main contract for the Hoover Dam, and Mr. Hart was made director. This company, with the cooperation of the J. F. Shea Company, also bid in the contract for the main piers of the Golden Gate Bridge. The award was made, but litigation ensued and no construction could proceed until July, 1932. Previous to that time the Pacific Bridge Company had been released from its bond. It elected to bid again for the work and was low bidder for the main piers in October, 1932.

Difficulties were to arise, however, which were to test the mettle of Mr. Swigert, Mr. Hart, and their associates, as men had rarely been tested before. The construction of the south pier of the Golden Gate Bridge has been characterized by the late D. E. Moran,[4] M. Am. Soc. C. E., as the most difficult foundation job ever undertaken. The specifications required pneumatic caisson construction but allowed only fifteen months for the completion of the work. In the hope of making good on these conflicting requirements, desperate expedients were resorted to in regard to building the caisson away from the site and making all the excavation in the open. The stormy season of 1933 found this company just ready to place the steel fender sections for the south pier in 100 ft of water. The Pacific Ocean, however, was soon to claim its own, and on October 31 the first fender sections were wrecked by a storm while being lowered. It became evident that a drastic revision of plans was necessary for success, but before the plans were completed another storm arose on December 13 and demolished the outer 700 ft of the company's access trestle to the south pier.

With the assistance of their consulting engineers, Moran and Proctor, new plans were made and approval obtained on the principle of making more use of underwater construction. In other words, there was to be no construction project above the water that could be ruined by a storm until the entire pier was completed to 17 ft below water. Then the fender wall was to be built up above the water a little at a time until finally the entire fender ring was completed and after that the shaft could be built inside of it. To Mr. Hart should be given full credit for knowing what his divers could do and for developing the construction methods for getting the fender up to and through the water. In April, 1934, the company succeeded in concreting its first fender section by this method. Quiet water was ahead that summer and Fortune smiled on the company, and the entire pier was completed about January 1, 1935.

---

[4] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 1840.

Previous to that time the company had participated in several syndicates organized for the large PWA jobs that were then appearing. They were a constituent company of the Transbay Construction Co. which executed the contract for the piers for the suspension spans of the San Francisco-Oakland Bay Bridge, and for the 85-ft extension of the O'Shaughnessy Dam for the City of San Francisco, Calif., water supply let in January, 1935. They also had an interest in the construction of the Bonneville Dam power-house foundation and power house by the General Construction Company and J. F. Shea Company, and in the construction of the Parker Dam across the Colorado River with the J. F. Shea Company.

The anxieties of the Golden Gate Bridge proved too much for Mr. Swigert and he died on June 23, 1935. Mr. Hart succeeded him as president of the Pacific Bridge Company. Contracts executed by the company under Mr. Hart were:

1935—Subaqueous pipe line for Hetch Hetchy water supply under Dumbarton Straits, San Francisco Bay.

1936—Concrete pier for Naval Ammunition Depot for the Bureau of Yards and Docks, Balboa, Canal Zone.

Concrete deck for the Golden Gate Bridge.

1937—Railroad facilities over the steel spans of the San Francisco-Oakland Bay Bridge.

In 1937 the Pacific Bridge Company participated with the George Pollock Company and other associates in the construction of Drydock No. 3, Mare Island Navy Yard, for the Bureau of Yards and Docks. Mr. Hart's company was the operating company and the work was not completed at the time of his death. In 1937 they became a constituent company of the Consolidated Builders, Inc., later engaged in the completion of the Grand Coulee Dam. They were also a part of the syndicate that constructed the San Francisco railway terminal building of the San Francisco-Oakland Bay Bridge.

In 1938 the Pacific Bridge Company headed the syndicate that held the contract for the Tacoma Narrows Bridge, the syndicate being known as the Pacific-General-Columbia, and was the active operating company for this work.

It was while returning to his headquarters in San Francisco from his home in Portland after signing this contract that he met his untimely death. In the wreck of the Portland-San Francisco plane off Pt. Reyes on the morning of

November 29 the waters he had conquered so often at last claimed him for their own.

Among the keenest ambitions of most constructive minds is to leave an organization that can carry on after the founder of the company is gone. This was so in the case of Mr. Swigert: the company's activities since 1935 prove that he erred not in choosing his successor. It is also true in the case of Mr. Hart, and the successful prosecution of the Tacoma Narrows Bridge contract without his leadership proves that the organization he worked so hard to establish can still carry on.

Mr. Hart's contributions to engineering must be appraised from his actions rather than his words. His professional writings were very meager. He was a pioneer in making a profitable business out of what a diver can do. It was his boast that his divers could do anything under water that the ordinary man could do on the land. He developed new methods for laying submarine pipe and was known as an authority on that subject by every corporation west of the Mississippi River that had submarine pipe to lay. This resulted not only in profits to his company, but in large savings to his company's customers. The company before him, and he himself, had done much to make the open caisson foundation of tremie concrete poured among piles the successful foundation procedure it is today. He had the confidence of many prominent engineers engaged in designing foundation works. How much of the success of such structures as the foundations of the Longview Bridge and the two San Francisco bridges is due to suggestions originating with him he would be far too modest to say. He knew the sawmill business, and two of his most noteworthy successes—the Portland harbor wall and the track construction of the San Francisco-Oakland Bay Bridge—arose from applying sawmill methods to the ordinary contractor's job.

As to Mr. Hart's mental processes, he was somewhat opportunistic; he could scarcely qualify as a high-class technical man familiar with the accomplishments of others through technical literature. Where would he find the time for research? Yet he possessed the ability to follow through a complicated train of thought without benefit of mathematical processes and he usually arrived more or less intuitively at the right answer. This ability to accomplish so much with so little apparent effort was at once the admiration and despair of those who tried to compete with him. The making of a contractor's estimate for a large job, getting all the elements in and properly valued, is a laborious undertaking. Mr. Hart had the faculty of making a few figures which no one else could understand and he usually came out with a low bid which "left nothing on the table." The difficulties he had in nearly every case arose from his relying too strongly on the judgment of others, or in not being able to prevail upon his associates as to what course to follow.

Mr. Hart cannot be judged fairly by ordinary professional standards. He had qualities of courage and dogged pertinacity for which the ordinary engineer can only sigh in vain. To grasp the Golden Gate south pier situation as it was in the winter of 1933, and overcome all the obstacles that stood in the way of success at a time when few people believed the pier could be built at all and in the face of certain ruin for his company in the event of failure, is an accomplishment which won him the admiration of the entire thinking community in San Francisco.

The difficulties others had in following him made him impatient with other men. In later years he became impatient with any but the swiftest means of transportation, and this quality, more than anything else, led to his untimely death. For one who had borne his heavy responsibilities for so many years, he was extremely youthful. May the spirit of eternal youth which he typified never perish!

He was married in 1913 to Milla Wessinger, of Portland, who survives him. He leaves three children, Philip, Jr., Louise, and Dixon. He was a member of the Benevolent and Protective Order of Elks.

Mr. Hart was elected a Member of the American Society of Civil Engineers on April 18, 1927.

RALPH STEVENSON HAWLEY, M. Am. Soc. C. E.[1]

DIED JULY 30, 1939

Ralph Stevenson Hawley was born in Hanford, Calif., on January 11, 1877. He was the son of Luther C. Hawley (born in Ohio on May 4, 1829), a Civil War veteran, and Alice (Muldrew) Stevenson (born in Kentucky on August 15, 1843) who were married in Vandalia, Ill., on November 23, 1865. Ralph was the fifth of ten children. Two brothers and a sister survive him.

Ralph entered the University of California at Berkeley, Calif., in August, 1899, and was graduated from the College of Civil Engineering in May, 1903, at commencement exercises, made memorable by the presence of President Theodore Roosevelt, in the then partly completed Greek Theater of the University.

Immediately after graduation he received an appointment as hydrographic aid (later assistant engineer) in the U. S. Geological Survey, and was assigned to water resources and reclamation studies in Owens Valley, California, from June, 1903, to October, 1904. He developed much of the data upon which the City of Los Angeles (Calif.) later based its estimates for the great Owens River Aqueduct. He was then transferred to Yuma, Ariz., until February, 1905, thence to Los Angeles for three months, and finally to Berkeley, where he served until April, 1907, principally on hydrographic work in northern California under W. B. Clapp.

In April, 1907, he was appointed assistant city engineer in the office of the city engineer of Oakland, Calif. In this employment he prepared specifications and plans for street construction, sanitary and storm sewers, and the salt-water fire protection system. In February, 1908, he was appointed city engineer of the contiguous town (later city) of Emeryville, Calif.

---

[1] Memoir prepared by Harold Farnsworth Gray, M. Am. Soc. C. E.

Mr. Hawley served the City of Emeryville for a little more than thirty-one years as city engineer, and in addition was superintendent of streets and assistant city clerk from 1909. As the city grew, practically all of the storm and sanitary sewers, the street work, and the general municipal improvements of the present city were designed and constructed under his supervision. In the aggregate these works ultimately amounted to an impressive total value, although no individual project of great size was included therein; but if, in the somewhat prosaic development of the steadily growing industrial community, no great works were built, the many smaller projects reflected the character of the man; they were designed on sound principles, were well and honestly built, and have endured effectively in service.

Ralph Hawley, however, was far more to his city than its engineer. Quietly and unobtrusively he accepted other public services which his fellow townsmen placed in his hands because they recognized his integrity and dependability, and turned naturally and confidently to him when there was community work which needed to be done. For others was the limelight and publicity; for him was the modest but effective labor which enabled these community projects to succeed.

For eighteen years he was clerk of the Board of Trustees of the Emery Unified School District. He was one of the organizers of the Emeryville Industrial Association in 1920, and served as its secretary until his death. He was appointed secretary-treasurer of the Emeryville Welfare Commission in 1926 and served as such continuously thereafter. In January, 1936, he was appointed a trustee of the Alameda County Mosquito Abatement District by the City Council. He was also vice-president of the Board of Trustees of the District in 1938, and was elected president of the Board of Trustees in January, 1939.

In June, 1937, he was elected president of the East Bay Engineers Club for the 1937–1938 club year. On January 11, 1939, he was installed as president of the Emeryville Kiwanis Club. In the Kiwanis Club he had the distinction of 100% attendance for ten years.

Mr. Hawley became a member of the First Presbyterian Church in Berkeley in 1899, and was continuously thereafter a member, serving as a Sunday School teacher and as an Elder. He was a sincere and consistent Christian, living the Golden Rule in every action of his daily life. This, with his kind, strong face and gentle manner, brought him affection and admiration, while his fine character inspired respect untinged by envy. At the news of his sudden and utterly unexpected death, the first thought of many was "I have lost a friend."

He was married to Elizabeth Duncan at Bishop, Calif., on November 7, 1903. Mrs. Hawley and their two daughters, Ethel June and Genevieve, survive him.

Mr. Hawley was elected a Member of the American Society of Civil Engineers on December 5, 1911.

WILLIAM CHAUNCEY HAWLEY, M. Am. Soc. C. E.[1]

Died December 10, 1939

William Chauncey Hawley was born in Cambridge, Washington County, N. Y., on August 31, 1865. He was the eldest child of Charles Townsend Hawley and Fannie (Warner) Hawley. The Hawley family came to this country from England in 1630, settling first in Connecticut and later in Vermont and New York. During the Revolutionary War they were Loyalists, and did not fight for the Colonies. However, Mr. Hawley's paternal grandmother and great grandmother brought in strains of Dutch and Scotch-Irish blood, and he had at least five ancestors who fought in the Revolution.

Mr. Hawley's earliest schooling was in Cambridge, but when he was only eight years old he was sent to the Academy at Salem, N. Y., where an uncle was headmaster. It was there that he prepared for college. He entered Rensselaer Polytechnic Institute at Troy, N. Y., and was graduated in 1886, before he was twenty-one, with the degree of Civil Engineer.

His first engineering experience was in the designing and building of the plant for the Cambridge Water Works Company in his home town. The plant is still being operated substantially as Mr. Hawley designed it in 1886–1887, and has proved successful, not only as a safe and dependable source of water supply, but as a sound financial investment for those who were interested in such a supply for a small village in the early days of water works.

From 1887 to 1893 Mr. Hawley was assistant and principal assistant to the late Chester B. Davis, M. Am. Soc. C. E., engaged on surveys, making plans and constructing various water works and sewage systems. The year 1893–1894 he served as assistant engineer on surveys and plans for additional water supply for Troy. The following year he was resident engineer on construction of water works at Grafton, W. Va., for Wilkins and Davison of Pittsburgh, Pa. In 1895, as assistant engineer to Robert Swan of Allegheny City, Pa., he designed the Montrose Pumping Station and 9½ miles of 60-in. riveted steel force main and later was in charge of construction of 6 miles of the latter. From 1896 to 1902, Mr. Hawley was engineer and superintendent for the Water Department of Atlantic City, N. J.; and from 1902 until his death, he acted as chief engineer, superintendent, and vice-president of the Pennsylvania Water Company at Wilkinsburg, Pa.

Mr. Hawley was Past-President of the Engineers' Society of Western Pennsylvania, a member of the American Water Works Association, New England Water Works Association, Past-President and member of the Executive Committee of the Pennsylvania Water Works Association. He was the author of many articles published in the water works journals.

On December 25, 1890, he was married to Nellie N. Newton. He is survived by his widow; one son, William Chauncey Hawley, Jr.; one daughter, Mrs. Margaret Hawley Ely; and four grandchildren.

---

[1] Memoir prepared by Charles L. Fox, M. Am. Soc. C. E.

Mr. Hawley was deeply religious, being a communicant of the Protestant Episcopal Church. At the time of his death he was a Vestryman of the Calvary Protestant Episcopal Church of Pittsburgh. His intimate knowledge of water works management made his advice sought by other leaders. He was a man of upright character and sterling qualities that endeared him to his fellowmen. His untimely sudden death is sincerely regretted by all who have had the privilege of his acquaintance and association.

Mr. Hawley was elected a Junior of the American Society of Civil Engineers on October 1, 1890; an Associate Member on April 6, 1892; and a Member on December 3, 1902.

JAMES CLARK IRWIN, M. Am. Soc. C. E.[1]

Died March 20, 1940

James Clark Irwin was born at Cheyney, Delaware County, Pa., on September 23, 1868, the son of William Henry and Catherine (Browning) Irwin. His preparatory education was received at the Protestant Episcopal Academy at Philadelphia, Pa. Entering the University of Pennsylvania, at Philadelphia, in 1886, he received the degree of Bachelor of Science in 1890 and the degree of Civil Engineer in 1891. While attending the University of Pennsylvania he held various class positions, and upon graduation was instructor in Civil Engineering for the year 1891–1892.

Mr. Irwin entered the service of the New York Central and Hudson River Railroad Company on July 1, 1892, in charge of construction of block signaling between Buffalo, N. Y., and Albany, N. Y. He continued in the service of the New York Central until his retirement from active service on October 1, 1938.

During Mr. Irwin's employment by the New York Central System he held the positions of assistant trainmaster, assistant superintendent of signals, superintendent of the Hudson River Bridge Company, division engineer, signal engineer, assistant to the general superintendent, superintendent of the Lake Erie, Alliance and Wheeling Railroad Company, engineering assistant on the staff of the vice-president, resident engineer and superintendent of construction on the Grand Central terminal improvements, and office engineer in charge of contracts. From 1909 to 1912 he served as chief engineer of the Rutland Railroad Company, and from 1912 to 1938 he was with the Boston and Albany Railroad Company, being valuation engineer from May, 1920.

Mr. Irwin was one of the pioneer engineers in modern railway signaling, one of the charter members of the Railway Signaling Club, predecessor of the Railway Signal Association (later the Signal Section, Association of American Railroads). He continued his active and helpful interest in railway signaling during his entire career.

---

[1] Memoir prepared by E. M. Hastings, M. Am. Soc. C. E.

He was elected a member of the American Railway Engineering Association in 1907 and was very active in its affairs. He served on the Committee on Uniform Contract Forms, being its chairman from 1927 to 1931; on the Committee on Standardization, being its chairman from 1931 to 1935; and was vice-chairman of the Committee on Rules and Organization at the time of his death. He served as a director from 1932 to 1935, vice-president from 1935 to 1937, and president from 1937 to 1938. As president of the A. R. E. A. he was chairman of the Engineering Division of the Association of American Railroads and did much to further the research in engineering matters for that association.

In 1930 Mr. Irwin was appointed to represent the Association of American Railroads Engineering Division on American Standards Association, Standards Council, and was elected chairman of the Standards Council for the three years 1933 to 1936. He was a member of the Board of Directors of the American Standards Association from 1934 to 1936, and ex-officio member of the Board and Council from 1937 to 1939. Mr. Irwin's thoroughness and unusual ability fitted him admirably for the exacting service he performed for the American Standards Association.

In all of the diversified work that he carried on for the railroad by which he was employed, for the associations he served, and for the organizations and committees he assisted, he exercised untiring effort and care; no task was too small nor too great to obtain his undivided interest and attention. Mr. Irwin found much time to devote to those other things of life, outside of his profession, that leave their mark on communities and individuals and live long after a life has passed beyond. For fifteen years he was a vestryman, junior warden or senior warden of St. John's Church, Newtonville, Mass. He was a member of the Episcopalian Club of Massachusetts; he served as a member of its council, as chairman of its membership committee, and as president in 1933. He was Scoutmaster, troop committeeman, district commissioner, and a member of the Greater Boston Council, Boy Scouts of America, from 1913 to 1933.

Mr. Irwin was active in New England affairs during the World War. He was chairman of the New England Committee on the Study of Military Mobilization in 1916 and 1917, and was a member of the Business and Professional Men's Military Battalion. From 1917 to 1920 he was chairman of "Troop C Home Folks" and "Home Association of the 102nd Machine Gun Battalion, 26th Division." In 1918 he was appointed by Governor McCall as a delegate from Massachusetts to the "Win the War" convention in Philadelphia. Three sons of Mr. Irwin served in the World War.

He was active in many other ways; among such activities he was:

Member of the New England Railroad Club, serving on its executive committee and as president;
Member of the New York Railroad Club;
Member of the Railway Guild (railway honorary society);
Life Member of The Episcopal Academy Alumni Society;
Member of The General Alumni Society, University of Pennsylvania, also serving as a member of the board and as vice-president;

Member of the Associated Pennsylvania Clubs, serving as president;
Member of the New England Alumni Society of the University of Pennsylvania, serving as president;
Member of the Committee on Annual Giving of the University of Pennsylvania;
Member of Academy of Political Science;
Member of National Security League; and
Governor of The University Club, Boston, Mass.

He was profoundly interested in young men; his kindly counsel and affectionate interest left its impression on many a young man and helped him over difficult places. Although those who knew him best admired greatly his professional attainments and respected his opinions and judgment, they loved him most for those sterling qualities of Christian character, moral integrity, high and noble purposes, and his love for home and family. It was always a privilege to be with him; truly it may be said that James Clark Irwin made the world a better place in which to live.

On June 5, 1895, he was married to Frances Smith Monaghan of West Chester, Pa. They had four sons, James C., Robert M., William H., and John, and one daughter, Katherine. Three sons, James, Robert, and John, and daughter, Katherine, together with Mrs. Irwin, survive him.

Mr. Irwin was elected a Junior of the American Society of Civil Engineers on April 4, 1893; an Associate Member on December 7, 1898; and a Member on June 6, 1900.

CHARLES WHITE JOHNS, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 16, 1939

Charles White Johns was born in Farmville, Va., on December 28, 1875. His parents were James M. and Pauline (Cassell) Johns, and his early education was received in the public schools of Farmville and Portsmouth, Va. After a term in business college, he concluded that his interest was in engineering and, under the tutorage of his uncles, C. M. Cassell and Virginius O. Cassell, engineers and architects of Norfolk, Va., he obtained his preliminary training.

His engineering experience began in 1891 when he took a position with the Norfolk, Wilmington and Charleston Railway Company, a projected line, as rodman and chainman on surveys. In 1893 he was employed as draftsman in the office of his uncles, and in April, 1898, became instrumentman with Graham and Riddle and later with Haenselman and Smith, both engineering firms of Norfolk. This gave him a varied experience in surveying, subdivision work, and sanitary and other general municipal construction projects.

---

[1] Memoir prepared by A. C. Copland, M. Am. Soc. C. E., and Crosby Miller, Assoc. M. Am. Soc. C. E.

It was in September, 1899, that he accepted employment in the engineering department of the Chesapeake and Ohio Railway Company and continued with that company for forty years. His first assignment was instrumentman on the construction of a grain elevator, a merchandise pier, and a coal pier, at Newport News, Va. In May, 1900, he was transferred to Richmond, Va., as assistant engineer on the joint passenger station of the Chesapeake and Ohio and Seaboard Air Line Railway Companies. This work included grade separation and the construction of a viaduct about 3 miles long which elevated the tracks along the bank of the James River in Richmond. In addition, his work embraced line and grade revisions of the division of the railway extending from Richmond to Clifton Forge, Va., and grade separation at Charlottesville, Va., with construction of yards and sidings.

In December, 1904, Mr. Johns was advanced to assistant division engineer at Hinton, W. Va., in charge of maintenance of branch lines in West Virginia, and in April, 1906, to division engineer of the Huntington and Greenbrier Divisions. Subsequently, he was advanced to the position of assistant engineer of maintenance of way at Huntington, W. Va., in charge of the maintenance of all lines of the railway in West Virginia.

Mr. Johns was promoted to engineer of branch lines, with headquarters at Richmond, in February, 1914. This led to the position of engineer of construction in August, 1920, and in January, 1923, to chief engineer, in which capacity he continued until his death.

Among the many important engineering works which were under his direction as chief engineer were large classification yards and engine terminal facilities at Clifton Forge; replacement of the Ohio River bridge at Cincinnati, Ohio, including separation of grades in Covington, Ky., and Cincinnati; enlarging old tunnels and constructing new ones to provide increased clearances for modern equipment and large shipments; a coal dumper on the dock at Presque Isle, Toledo, Ohio; a coal pier and dumper at Newport News for unloading coal from railroad cars to ships; large locomotive shops at Huntington; and car shops at Russell, Ky. In later years the separation of grades of railroads from highways and city streets occupied his attention in a large measure.

Mr. Johns had an agreeable disposition, always courteous and kindly, which resulted in his having many friends among his acquaintances in the railroad business as well as other interests with which his work brought him in contact. He was considerate of all, especially his immediate associates, and this inspired their greatest respect.

Mr. Johns was an active member of the American Railway Engineering Association, having served on many of its committees and being a member of the committee on rail at the time of his death. He was also a member of the committee on steel of the American Society for Testing Materials. He was actively interested in the Virginia Section of the American Society of Civil Engineers and was vice-president from 1936 to 1938, becoming president in January, 1939. He was a member of St. Pauls Protestant Episcopal Church of Richmond and the Acca Temple Shrine, Ancient Arabic Order, Nobles of the Mystic Shrine.

He was married to Delia H. Brooke of Portsmouth, who, with a daughter, survives him.

Mr. Johns was elected a Member of the American Society of Civil Engineers on June 1, 1925.

ARTHUR NEWHALL JOHNSON, M. Am. Soc. C. E.[1]

DIED JULY 11, 1940

Arthur Newhall Johnson was born in Lynn, Mass., on November 11, 1870, the son of David Newhall and Amanda Malvina (Richardson) Johnson. His technical education was obtained at the Lawrence Scientific School of Harvard University, at Cambridge, Mass., from which he was graduated in 1894 with the degree of Bachelor of Science in Civil Engineering.

During the academic year 1896–1897 he served as instructor in Descriptive Geometry at Harvard. He left the teaching position to become assistant engineer at the Calumet and Hecla Mine at Calumet, Mich. In 1897 he joined the engineering staff of the Massachusetts Highway Commission. At that time the organization was engaged in its pioneer efforts that led to modern highway construction.

In 1898 he was called by the Maryland Geological Survey to make a survey of road conditions and road building materials in that state. In the seven years he spent in Maryland he made a thorough study of the road building resources of the state, built demonstration macadam roads, and so thoroughly promoted the good roads movement that in later years Maryland became one of the " best roaded " states in the Union.

In recognition of his successful work in Maryland, in 1905 Mr. Johnson was invited to become chief engineer of the newly established United States Office of Public Roads in Washington, D. C., later the Public Roads Administration. After serving a year in this position, he was named state highway engineer of Illinois, where he laid the beginnings of the excellent system of highways in that state.

From 1914 to 1916 he was highway engineer of the New York Bureau of Municipal Research. He left that organization to become consulting highway engineer for the Portland Cement Association. After four years in this position, he resigned to become Dean of the College of Engineering at the University of Maryland, at College Park, Md. He reorganized the engineering courses and established the Maryland Engineering Experiment Station. In cooperation with the U. S. Bureau of Public Roads, and the Maryland State Roads Commission, he conducted research studies on highway traffic, and on the strength and elastic properties of concrete, particularly as related to its use in road construction. His ability as a teacher and his kindly manner endeared him to all his students.

---

[1] Memoir prepared by S. S. Steinberg, M. Am. Soc. C. E.

He was author of a number of technical papers and reports. He was a member of the American Society for Testing Materials and of the Highway Research Board of the National Research Council, serving as chairman of the Executive Committee of the latter group from 1923 to 1926. He served as president of the American Association of Engineers in 1922. He was a member of the Cosmos Club in Washington, D. C., and a member of Tau Beta Pi.

On two occasions he represented the United States in conferences held abroad. In 1913 he was delegate to an international highway conference in Paris, France, and in 1925 he was appointed, by President Coolidge, a member of the American delegation to the Pan-American Road Conference in Buenos Aires, Argentine Republic.

In 1924, the University of Maryland, in recognition of his achievements in highway engineering, and particularly of his pioneer work in Maryland, conferred on him the honorary degree of Doctor of Engineering.

In 1932, Dean Johnson was the recipient of the Bartlett Award presented annually "for outstanding contribution to highway progress." The selection for this award is made by a committee consisting of the presidents of the American Road Builders' Association, the Association of State Highway Officials, and the Highway Research Board of the National Research Council.

In the passing of Dean Johnson, the profession has lost one of its pioneers in modern highway development. In the course of his long career in the highway field, it fell to his lot to train many men, some of whom became the outstanding highway engineers in the profession.

In 1936, due to continued ill health, Dean Johnson found it necessary to retire from the University, having served sixteen years as Dean of the College of Engineering.

He was married to Mae Louise Ash on September 12, 1900. He is survived by his widow and three daughters, Louise N. (Mrs. Lewis P. Shanks), Evelyn N., and Mary W. Johnson.

Dean Johnson was elected an Associate Member of the American Society of Civil Engineers on September 2, 1903, and a Member on July 1, 1909.

RICHARD KHUEN, JR., M. Am. Soc. C. E.[1]

DIED SEPTEMBER 24, 1938

Richard Khuen, Jr., was born at Saginaw, Mich., on July 27, 1865, the son of Richard and Caroline (Scheib) Khuen.

After graduating from the University of Michigan, at Ann Arbor, Mich., in 1889, with the degree of Bachelor of Science in Civil Engineering, he entered the employ of the late George Shattuck Morison,[2] Past-President, Am. Soc. C. E., with whom he remained until August, 1891. From July,

---

[1] Memoir prepared by Marshall Williams and C. F. Goodrich, Members, Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LIV, June, 1905, p. 513.

1889, to October, 1890, he was assistant engineer on the construction of the Merchants Bridge, St. Louis, Mo.; from July to October, 1890, assistant engineer on the construction of the Memphis Bridge, Memphis, Tenn.; and from October, 1890, to January, 1891, draftsman in Mr. Morison's Chicago office. From January to June, 1891, he was assistant inspector of steel superstructure of the Memphis and Winona bridges at Union Bridge Company, Athens, Pa., and from June to August, 1891, he was inspector of steel superstructure of Memphis Bridge at Pennsylvania Steel Company, Steelton, Pa.

In August, 1891, he took the position of bridge inspector and assistant engineer for the New York, Lake Erie and Western Coal and Railroad Company. In November, 1892, he became assistant engineer for the Quaker City and North Eastern Elevated Railroads in Philadelphia, Pa., where he remained until July, 1893. During this period the service was under the late Carl Waldemar Buchholz, M. Am. Soc. C. E.

In July, 1893, Mr. Khuen entered the service of the bridge and construction department of the Pencoyd Iron Works (A. and P. Roberts Company) at Pencoyd, Pa., as assistant engineer in charge of estimating and designing, under the late Charles Conrad Schneider,[3] Past-President, Am. Soc. C. E. From February to May, 1898, he was resident engineer for the Pencoyd Iron Works during the erection of the Niagara Falls-Clifton Bridge (840-ft arch span). This bridge was destroyed by the ice in January, 1938.

In February, 1901, following the merging of the Pencoyd Iron Works with the American Bridge Company in May, 1900, Mr. Khuen was transferred to Pittsburgh, Pa., where he held the position of Pittsburgh division engineer for the American Bridge Company. On May 18, 1914, he was appointed general manager of erection, succeeding the late Emil Gerber,[4] M. Am. Soc. C. E. On April 1, 1931, he was appointed chief engineer, succeeding the late James Harvey Edwards,[5] M. Am. Soc. C. E.

He retired from active service with the American Bridge Company on July 1, 1935, shortly before his seventieth birthday. After his retirement, and until his death, he maintained an office as consulting engineer in Pittsburgh.

All branches of bridge and structural engineering benefited from the influence of his efforts and activities. He accommodated himself to the many advancements in design, detail, materials, and methods which took place during his many years of engineering, and, in many instances, took a leading part in the transition. A statement of the outstanding structures that passed through his engineering and erecting administrations is much too long for publication. They cross the streams and dot the landscape in all parts of the United States and in numerous foreign countries. They are representative of the strength of affection and high regard that he built in the hearts of his friends and associates.

His entire professional life was spent in bridge and structural work. He was well founded technically and was also endowed with a keen commercial sense, which made him an ideal engineer—"one who produced the greatest return on the dollar invested." He was freely consulted by his fellow engineers and cheerfully contributed from his great fund of engineering knowledge, gained over a long term of experience. He was a quiet, genial gentleman who enjoyed social contacts with those whom he accepted as worth while. He was rather strong in his likes and dislikes, an attribute which led to a careful selection of those whom he chose to "grapple to thy soul with hoops of steel." He adopted a strict code of social and business integrity, was a capable engineer, a successful administrator, and an honorable, enjoyable gentleman at all times.

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXI, December, 1917, p. 1665.

[4] For memoir, *loc. cit.*, Vol. LXXIX (1915), p. 1418.

[5] For memoir, *loc. cit.*, Vol. 96 (1932), p. 1463.

In 1895 Mr. Khuen was married to Elizabeth Meason, of Greensburg, Pa. She died on February 10, 1929. A son, Richard Khuen, III, two sisters, and a brother survive him.

Mr. Khuen was a member of the American Railway Engineering Association; the Engineering Society of Western Pennsylvania; the Railway Club of Pittsburgh; the Metropolitan Club of Pittsburgh; the Edgeworth Club of Sewickley, Pa.; and the Montour Heights Golf Club, at Coraopolis, Pa. He was a director of the Engineering Society of Western Pennsylvania for the years 1922–1924, and served on a number of important committees during his long term of membership. In 1917 he was the organizer, founder, and first President of the Pittsburgh Section of the American Society of Civil Engineers, and his interest did not relax during his lifetime.

Mr. Khuen was elected Director of the American Society of Civil Engineers for the term 1916–1918, and was the candidate for Vice-President from Zone II on the first ballot at the time of his death. He was a regular attendant at the Society conventions and gave unstintingly of his time and effort to committee and other work that presented itself in the Society's activities.

Mr. Khuen was elected a Junior of the American Society of Civil Engineers on December 3, 1891; an Associate Member on May 1, 1895; and a Member on November 2, 1898.

PHILIP GEORGE LANG, JR., M. Am. Soc. C. E.[1]

Died December 9, 1939

Philip George Lang, Jr., was born in Philadelphia, Pa., on September 24, 1883, the son of Philip George Lang and Marie Louise (Beck) Lang.

He received his early education in the public schools of Philadelphia, and in the North East Manual Training School, graduating from the latter in June, 1901. In the succeeding autumn he entered the University of Pennsylvania, at West Philadelphia, Pa., where he successfully completed the four-year engineering course, and was graduated in June, 1905, with the degree of Bachelor ot Science in Civil Engineering. In June, 1922, he received the postgraduate degree of Civil Engineer from that University.

---

[1] Memoir prepared by a Committee of the Maryland Section consisting of C. E. Sloan, H. A. Lane, and E. J. Dougherty, Members, Am. Soc. C. E.

Shortly after graduation Mr. Lang became a draftsman in the Pencoyd Plant of the American Bridge Company. On March 16, 1906, he entered the service of the South and Western Railroad (later Carolina, Clinchfield, and Ohio Railway Company), at Johnson City, Tenn., as designer. On December 4, 1907, he entered the organization of The Baltimore and Ohio Railroad Company, as assistant engineer, at Baltimore, Md.

During the succeeding decade, while engaged in a variety of duties connected with the design, construction, and maintenance of bridges, he acquired diversified experience and intimate knowledge of every portion of the System. For several years part of his time was devoted to making field measurements and preparing record sketches of bridges. This field experience was alternated with long periods in the Bridge Drafting Room, at Baltimore.

In 1915 construction work was begun on the great Export Coal Pier of The Baltimore and Ohio Railroad Company, at Curtis Bay, near Baltimore. These facilities were unique as to magnitude and character of equipment. Mr. Lang was intimately associated with this work, and also with the design and construction of mechanical trimmers for the stowing of coal and other bulk material in the cargo space of vessels; four such devices were installed at the Curtis Bay Terminal between December, 1919, and April, 1920.

On May 1, 1917, he became chief bridge draftsman, and discharged the duties of that office until August 1, 1918, when he was advanced to the position of assistant engineer of bridges. On May 1, 1921, he was appointed engineer of bridges of The Baltimore and Ohio System.

During the World War railroad bridge work was attended by numerous major difficulties, but, within this trying period, every phase of the tasks committed to Mr. Lang's charge proceeded to a successful conclusion. In 1919 The Baltimore and Ohio Railroad Company commenced the reconstruction of its Main Line bridge across the Allegheny River, at Pittsburgh, Pa. In this work Mr. Lang discharged an active rôle. The structural and operating problems were peculiarly difficult and complex, involving the construction of the new bridge at a level about 15 ft higher than that of its predecessor. Real estate conditions and War Department restrictions limited the working space, and major operations were concluded by the jacking of the main spans a vertical distance of about twelve feet. This project is the subject of an excellent paper by Mr. Lang.[2]

During the summer of 1920 work was commenced on the reconstruction of the railroad bridge across the Great Miami River, Lawrenceburg, Ind. This project was completed in the autumn of 1921. Between 1920 and 1929 The Baltimore and Ohio adopted annual programs of bridge reconstruction which involved a total of more than one thousand separate structures and an aggregate expenditure of approximately $30,000,000. Among the large projects with which he was associated during this period were the reconstruction of the railroad bridge across the Little Kanawha River, Parkersburg, W. Va., and that across the Allegheny River, Foxburg, Pa., and major grade separation projects at Millvale, Pa., Bond Hill, Ohio, and Chicago, Ill. Unique problems were presented by the reconstruction of the bascule bridge across the South Branch of the Chicago River, in Chicago, where the new bridge was built at a low level, and subsequently raised to final elevation, a distance of about 11 ft, by hydraulic jacks.

---

[2] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1152.

Objects of Mr. Lang's care included devices for the transfer of coal, ore, and other bulk materials at ports on the Atlantic Seaboard and Great Lakes. During 1924 he supervised the construction of a large ore bridge at Lorain, Ohio. As a result of his studies new and improved devices, designed to facilitate the transfer and prevent breakage of coal, were installed at several waterside points. He supervised the construction and installation of 115-ft turntables at several points on The Baltimore and Ohio System, where it became necessary to replace shorter tables. For several years he served as chairman of the Turntable Sub-Committee appointed by the Iron and Steel Structure Committee of the American Railway Engineering Association, the result of whose labors is represented in the Turntable Specification of 1924, which is still current.

The depression, which commenced in the autumn of 1929, necessitated the adoption of methods and appliances designed to minimize costs and extend service-life of facilities, and several projects involving the rehabilitation of metallic bridges by welding were completed under Mr. Lang's supervision, including an extensive program of welded repairs to the superstructure of the large bridge crossing the Susquehanna River, at Havre de Grace, Md., completed during the late autumn of 1938. From 1935 to 1939 he directed the designing and erection of more than one hundred and fifty bridges in connection with grade separation projects at various locations on The Baltimore and Ohio System. In central West Virginia the construction of a large dam in the Tygart River necessitated extensive line change, including the construction of numerous bridges. During his final years Mr. Lang devoted his attention to these projects and their associated problems.

Apart from the routine duties of his office, Mr. Lang's activities ranged through an extensive field. For many years he was a member of the American Railway Engineering Association, serving on its Iron and Steel Structure Committee. He was a member of the American Standards Association, directing his efforts especially along the lines of rivet standardization. In March, 1937, that organization published recommended rivet head standards, which seem likely to acquire general acceptance in the United States.

For twelve years he served as Chairman of the Joint Committee on Federal Valuation of Railroad Bridges. Under his skilful guidance this work was conducted through its initial stages, and its creative accomplishment is represented in a series of reports embodying essential data for the use of workers in the field of railroad valuation.

Structural welding early engaged his attention. Entering the American Welding Society, he was appointed chairman (in 1934) of the committee charged with the task of preparing specifications for the design and construction of metallic bridges with welded jointures. Under Mr. Lang's chairmanship this committee selected the best features of American and foreign practice, and embodied these in a specification, published in 1936, and since appearing in new and amended editions. A thorough discussion of the application of welding to metallic bridges, written by Mr. Lang, forms a chapter in the "Welding Handbook," published by the American Welding Society in 1938. In October, 1937, the American Welding Society elected him to serve as its president during the succeeding year.

Mr. Lang was connected with the Society for twenty-eight years and, at the time of his death, held membership in its Committees on Structural Alloy and Heat-Treated Steels and Movable Bridges. During the term 1935–1936 he served as President of the Maryland Section. He was a member of the Engineers Club of Baltimore, serving as its president for the 1937–1938 term. His contributions to professional literature are represented in about seventy papers and articles, appearing in the technical press. He served as editor of the "Railway Engineering and Maintenance Cyclopedia," Editions of 1926, 1929, and 1939, published by Simmons-Boardman Publishing Corporation.

Models of railroad bridge types, representative of practice from the beginning of the railroad era in the United States to the present day, built under Mr. Lang's direction for exhibition at The Baltimore and Ohio Centenary Celebration in 1927, were displayed subsequently at the Century of Progress Exposition in Chicago, and finally at Rockefeller Center, in New York, N. Y.

The social side of Mr. Lang's life was represented by membership in various masonic bodies, and in Boumi Temple, Nobles of the Mystic Shrine, at Baltimore, for which latter organization he served as a Trustee. A lifelong member of the Lutheran Church, he served several terms as an elder.

Because of his mastery of technical details, his integrity, sincerity, and activities in working for the advancement of knowledge and practice with respect to all phases of bridge building, he was recognized by his engineering associates as an outstanding member of the profession.

He was blessed with a genial and companionable personality, and was essentially interested in his home, family, and a wide circle of friends. He was prominent and active in community affairs, and his ability and judgment were always recognized and respected by his associates. He became an enthusiastic and discriminating philatelist, leaving a valuable and well-arranged collection of stamps. He was interested in art, and made a collection of original etchings by leading foreign and American artists. He developed a fine library in the field of general literature, which also included numerous authoritative works on the ancient and modern history of his profession.

In January, 1907, Mr. Lang was married to Eugenie Marie LeFort, of Philadelphia, who, with one daughter, Eugenie (Mrs. Robert Carey Reeder, Jr.), survives him.

Mr. Lang was elected an Associate Member of the American Society of Civil Engineers on October 3, 1911, and a Member on November 21, 1921.

WILLIAM DOMINICK LARRABEE, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 13, 1939

William Dominick Larrabee was born on February 21, 1849, at Horicon, Wis., one of the nine children of William Morse and Mary Margaret (Haight) Larrabee. When he was about one year old his family moved to Chicago, Ill. There William Larrabee's youth was spent in an atmosphere of railroad administration, for his father was secretary of the Galena and Chicago Union Railroad Company, and, later, secretary and treasurer of the Chicago and Alton Railroad Company. Of this latter railroad, William Dominick Larrabee was cashier and paymaster from 1873 to 1885. During this time he studied technical subjects, and advanced what he termed his "self education."

In 1887 Mr. Larrabee went to Los Angeles, Calif., and was employed on survey work by the late Edward Thomas Wright,[2] M. Am. Soc. C. E. In 1888 he was in charge of construction of three miles of cable road for the Temple Street Cable Railway of Los Angeles. In 1889 he was a draftsman in the city engineer's office and was a deputy under the city engineer (Los Angeles). He also, with Wright, Meysenburg and Company, contractors, was in charge of construction of 10 miles of cable railroad for the Los Angeles Cable Railway Company. From 1890 to 1893 he was with the Los Angeles Consolidated Electric Railway Company, first in charge of construction of 20 miles of electric railway, and later chief engineer in charge of maintenance of way and construction departments, including the construction of 30 miles of electric railway. In 1894 and 1895 he was chief engineer of the Pasadena and Los Angeles Electric Railway, having charge of preliminary surveys, location, and construction from Los Angeles through Pasadena, Calif., to Altadena, Calif. (about 40 miles, with local system at Pasadena).

For the next two years he was superintendent and chief engineer of the Pasadena and Los Angeles Electric Railway and the Pasadena and Pacific Railway in charge of the operating and construction departments. From 1897 to 1905 he was superintendent and chief engineer of the Pasadena and Pacific Railway and its successor company, the Los Angeles-Pacific Railroad Company. This was a period of great expansion in the interurban transportation system in Los Angeles and its environs, and Mr. Larrabee supervised all preliminary surveys and locations, had charge of all construction of the system (about 150 miles of track with various branches), made plans and supervised erection of the power station and car shed at Sherman (later West Hollywood), Calif., and supervised erection of various substations. In February, 1903, he was appointed chief engineer of the Beach Land Company, where he designed and constructed a dam across a channel 200 ft wide, with tide and flush gates for holding ocean water in a lagoon, and constructed two piers out into the Pacific Ocean (400 ft and 1,500 ft long). His retirement from this position followed the acquisition of the Los Angeles-Pacific Railroad Company by the Pacific Electric Company in 1905.

---

[1] Memoir prepared by Harry W. Dennis, M. Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXI, December, 1917, p. 1791.

In January, 1906, Mr. Larrabee joined in the incorporation of the United Railways Company. It was intended to construct a railroad from Portland, Ore., to Peak, Washington County, Ore. In February he became vice-president and general manager. The United Railways projected several electric lines in the vicinity of Portland, and Mr. Larrabee made a location survey for a railroad from Portland to the base of Mount Hood. He resigned from the United Railways Company in August, 1906.

Another electric railway venture in which Mr. Larrabee was interested was known as the Redlands and Yucaipa Electric Railway near Redlands, Calif. Of this project, Mr. Larrabee was general manager and chief engineer, and, although a preliminary location was made, it did not progress beyond the promotional stage.

For several years Mr. Larrabee was in Los Angeles as a consulting engineer in private practice and then, in 1918, he entered the employ of the Southern California Edison Company, Ltd., of Los Angeles. This engagement was for a specific problem of railroad location in rugged country as a part of a power development program in the High Sierras. Although the location work was completed, the line was not constructed. Nevertheless, Mr. Larrabee was retained by that company due, among other things, to his wide acquaintance and his ability and tact in handling many special matters, particularly in public relations, and in the acquisition of rights of way. In 1934, in accordance with the terms of the Edison Company's pension plan, he was relieved of further active duty.

Mr. Larrabee was married, at Parsons, Kans., on July 21, 1873, to Mary Adelia Bemis. To them were born three children, Marion B., Mary W., and John S. Larrabee, no one of whom has survived. Mrs. Larrabee died February 5, 1933.

Mr. Larrabee was a member of John Marshall Lodge No. 636, Free and Accepted Masons (West Hollywood, Calif.), and of the Lions Club (West Hollywood, Calif.). He had served as secretary of the West Hollywood-Sherman Civic Association, and as director of the West Hollywood Chamber of Commerce.

In national politics Mr. Larrabee was a Republican who gloried in the fact that, quoting from one of his own letters, "* * * in 1856 I was old enough to make a big noise for our first presidential candidate, John C. Fremont, and have hollered loudly for all our candidates since."

Mr. Larrabee was elected a Member of the American Society of Civil Engineers on October 5, 1904, and became a Life Member in 1929.

ARTHUR HERMANN MARKWART, M. Am. Soc. C. E.[1]

DIED JANUARY 25, 1940

Arthur Hermann Markwart was born at Duquoin, Ill., on February 13, 1880, the son of Hermann and Sarah (Beck) Markwart. When a boy he was brought to California by his widowed mother, his father having died when the son was eight years of age. His mother died when he was thirteen. There were two younger brothers, the care of whom devolved upon the elder boy.

Mr. Markwart's early education was obtained in the public schools and at the California School of Mechanical Arts, in San Francisco, Calif. In October, 1900, he entered the University of California, at Berkeley, Calif., graduating in December, 1903, with the degree of Bachelor of Science in Civil Engineering. While a student at The California School of Mechanical Arts, young Markwart maintained himself by work at the school. Upon graduation from that institution in 1899 he went on a trip to the Philippine Islands on a transport, where the Spanish War was then being brought to a close. When he returned he was employed as chief draftsman in the Judson Manufacturing Company and retained that position during the three years at the University. With the aid of assistants he worked on bridges, transmission towers, and other structural work.

After graduation, Mr. Markwart was employed by the Pacific Construction Company, contractors and engineers, as engineer on highway bridges (fixed and swing spans), trestles, reservoirs, and general work on both design and estimates of cost.

In September, 1904, Mr. Markwart was employed by the California Gas and Electric Corporation (later the Pacific Gas and Electric Company) as engineer making efficiency tests on water-wheel generator units, and assisted in preparing layouts and installation of three 5,400-hp gas engine generator units. He was also in responsible charge of the plans for the gas, air exhaust, and water piping of this installation. Later he was appointed assistant civil engineer for this corporation and as such had charge of civil engineering work on various structures, pole and pipe lines.

From February, 1906, to January, 1907, Mr. Markwart was chief engineer and manager of the Syndicate Water Company, of Oakland, Calif., and was also vice-president and manager of the Richmond Water Company, an affiliated organization. As such he was engaged in investigation of water resources on San Pablo and Wild Cat Creeks and the design and installation of water works and distribution systems for Richmond and Piedmont, Calif. He organized the water business of these two cities and established them as going concerns.

This engagement terminated when the two water companies were incorporated with an older company and Mr. Markwart became a member of the firm of Howard and Galloway, Architects and Engineers of San Francisco. The firm had charge of the design and construction of buildings in San Francisco and vicinity costing more than $3,500,000. They were architects of the Alaska-Yukon-Pacific Exposition of 1909 in Seattle, Wash., in connection with which three buildings and a power plant were built for the University of Washington at a cost of more than $2,000,000. Mr. Markwart organized and administered the Seattle office of the firm until the completion of the work.

---

[1] Memoir prepared by John D. Galloway and I. C. Steele, Members, Am. Soc. C. E.

The firm of Howard and Galloway was dissolved, and the firm of Galloway and Markwart, Consulting Civil Engineers, was organized in November, 1908, and continued in this form, with intermissions, until November, 1920. During the years 1909 to 1912 the firm made numerous reports of hydroelectric plants, irrigation systems, and similar projects, and designed and constructed bridges and building frames and foundations involving about $4,000,000. The principal hydroelectric work was in connection with the Oro Electric Corporation, later a part of the Pacific Gas and Electric Company.

Mr. Markwart suspended professional activity in the firm in July, 1912, and until April, 1915, had general charge of construction at the Panama-Pacific International Exposition, as chief of construction and assistant director of works. These activities included executive work and engineering management, and involved varied engineering studies, construction programs and estimates, the drawing of construction contracts, the development and control of a construction budget amounting to $15,000,000, and the preparation of the rules and regulations of the Division of Works and their enforcement.

In April, 1915, Mr. Markwart resumed private practice in the firm of Galloway and Markwart, doing engineering work of the same general character as that in the period 1908 to 1912. Among other works the firm designed and constructed a hydroelectric plant for the United States Government in Yosemite Valley.

During the World War, when Mr. Galloway was called to France, Mr. Markwart conducted the business of the firm alone. He completed the construction of the hydroelectric plant in Yosemite Valley and other unfinished work of the firm, did engineering work of a general character, made reports on ship plant financing, as the representative for bondholders, and acted as general manager of the Clyde Company on behalf of the U. S. Shipping Board Emergency Fleet Corporation, spending approximately $1,000,000.

In the years when Mr. Markwart was in practice alone he acted at different times as consulting engineer or did work of engineering and management for the following organizations: The Panama-Pacific International Exposition, United States Department of Interior, the Ordnance Department of the Army and the U. S. Shipping Board Emergency Fleet Corporation, the Northern Electric Railway Company, Tillotson and Wolcott, investment bankers of Cleveland, Ohio, Foundation Company of New York, Syndicate Water Company, Pacific Gas and Electric Company, and the Bethlehem Shipbuilding Corporation.

On the return of his associate from France in February, 1919, the partnership of Galloway and Markwart was resumed. They engaged in the usual practice of civil engineering, involving irrigation system reports, financial representation, design and construction of water works, sewer systems, and similar works. They acted as consulting engineers and rendered engineering and supervisory service of a varied character to the following organizations: Oro Electric Corporation, Great Western Power Company, Turlock Irrigation District, Merced Irrigation District, Northern Electric Railway Company, and the United States Government.

The Pacific Gas and Electric Company engaged Mr. Markwart in November, 1920, and he continued in this service for nearly twenty years—until his death in 1940. The management of the company adopted an extensive program of hydroelectric development. It realized the need of a department, the major activities of which would be directed especially to technical investigations and planning, as distinguished from the construction and operation of the company's properties. As a result the Department of Engineering was organized. Because of his outstanding ability as an executive and an engineer, Mr. Markwart, on November 1, 1920, was employed as director of engineering to organize and conduct this work. Subsequently, in January, 1922, he was promoted to the position of vice-president in charge of engineering, and became an administrative and management officer of the company. He was charged with the responsibility for the design of all hydroelectric plants and water supply, steam plants, and substations; transmission and distribution lines; water pumping and collections systems; street railways; the designs or specifications for all electric switches, transformers, and meters; the preparation of standards governing all phases of engineering work; and research work including testing and inspections. His organization recently contained about 200 engineers and technicians.

In this capacity Mr. Markwart prepared programs for meeting future power demands of the company and developed comprehensive schemes for the production, transmission, and distribution of electric energy. These studies embraced most of the important rivers in northern California and several steam-plant projects.

During the twenty years of his employment, Mr. Markwart directed the engineering on work costing about $300,000,000. Comprehensive studies and location of projects for the Pit, Feather, and Mokelumne River hydroelectric developments were undertaken, including related transmission and distribution facilities. The proposed ultimate capacity of these three developments totals 1,376,000 kva, of which 459,000 kva have been installed.

Major construction work included the following: The completion of the Hat Creek No. 1 and No. 2 and Pit No. 1 hydroelectric plants, construction of which was started prior to Mr. Markwart's employment; the Pit River No. 3 plant of 81,000-kw capacity; the 202-mile 220-kv transmission line from Pit River to a main step-down and synchronous condenser substation near Vacaville, Calif., this being the first 220-kv transmission line ever designed and constructed; the Salt Springs and Tiger Creek projects on the Mokelumne River of 71,000-kw capacity; the Melones tunnel and power house of 27,000-kw capacity; the installation of two 50,000-kva turbo-generators and three boilers to operate at 1,400-lb pressure at steam Station "A," San Francisco, these being the first high pressure installations in the West; the reconstruction of steam Station "C," Oakland, including new high pressure boilers and a 50,000-kva turbo-generator, a group of four substations to supply power for electric train operation over the San Francisco-Oakland Bay Bridge, and power to the Golden Gate International Exposition; the installation of three new 50,000-kva steam turbo-generator plants to be completed in 1940.

Notable among the individual structures built under Mr. Markwart's engineering direction are: The Salt Springs Dam on Mokelumne River, this being the highest rock-fill dam in existence; Pit River Dams No. 3 and No. 4, concrete gravity-type dams on unusual foundations; Tiger Creek Forebay Dam, a reinforced concrete flat slab and buttress type; Tiger Creek Afterbay and Lyons Dams which are concrete arch structures; the Philbrook Dam which is a rolled earth structure; the 4-mile Pit No. 3 concrete-lined tunnel through lava formations; the 11½-mile Stanislaus tunnel; and the seventeen-story general office building of the company in San Francisco.

As an executive, economist, and an engineer, Mr. Markwart's work with the company was outstanding. His integrity, broad vision, brilliance of mind, and fairness commanded the respect and admiration of those who were associated with him during his twenty years of service.

At various times Mr. Markwart contributed valuable papers and discussions to numerous technical and educational organizations. Principal among these are:

"Regional Review of Power Resources, Distribution and Utilization for Pacific Coast States, U. S. A.," prepared jointly with the late H. A. Barre for the World Power Conference of 1924.

"Power in California" for the Franklin Institute of Philadelphia (August, 1927).

"Aspects of Steam Power in Relation to a Hydro Supply" for the American Society of Mechanical Engineers (1926).

"Pumped-Storage Hydro-Electric Plants" for the American Society of Civil Engineers (1929).[2]

"The Philosophy of Private Ownership of Public Utilities" for the Commonwealth Club, San Francisco (1929).

"Recommendations for Legislation and for Application of Law" for the Power Division of the American Society of Civil Engineers (1930).[3]

"The Future of Water Power Development in California" for the National Electric Light Association Convention, San Francisco (1930).

"Power Development on the Pacific Coast, Its Immediate Future" for *Electric Light and Power* (1935).

"Power Surplus in California" for *Electrical West* (1934).

---

[2] Discussion by A. H. Markwart of "Pumped-Storage Hydro-Electric Plants," by William W. K. Freeman, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 911.

[3] Published as part of the Symposium on "Public Supervision of Dams," *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 828.

"Mingled Hydro and Steam Power Production in California—Past, Present and Future" for the American Institute of Electrical Engineers' National Convention, San Francisco (June, 1939).

Mr. Markwart's activities extended into the business world, where he was a member of the Board of Directors of the Russ Building Company, The North American Investment Corporation, and the Commonwealth Investment Company. He was also a director of the San Francisco Remedial Loan Association (a charitable organization). In 1922 he became a member of the Board of Trustees of the California School of Mechanical Arts, from which he had graduated as a young man. In 1933 he became President of the Board, a position that he held at the time of his death.

He was a member of the Astronomical Society of the Pacific, and a member and past-president of the Pacific Coast Electrical Association. He was affiliated with the Phi Delta Theta fraternity and the Sigma Xi honor society; and a member of the Olympic, Bohemian, and Engineers clubs of San Francisco, of the Commonwealth Club of California, and of the Bankers Club of New York.

Mr. Markwart was married to Marie L. Chesebrough, on May 26, 1908, and she, with four sons, Arthur Jr., Henry Chesebrough, John, and Philip Gordon, survives him. A daughter, Elizabeth, is deceased.

This is a brief record of the life work of an intensively active man, whose death occurred all too soon. It is a signal example of how a poor boy, left an orphan at an early age, without relatives or position, worked constantly upward to a high position in the business and social world of the West. Untiring industry and an exceptional mentality, accompanied by a most pleasing personality, explain his success. Wherever he went, and in all of his occupations, his personal charm made friends of all with whom he dealt. One of his most salient characteristics was the sense of absolute honesty, integrity, and justice that pervaded all of his contacts with his associates and with the public. His departure leaves a gap in the engineering and financial world and to his close associates a sense of great loss, especially to those who have prepared this memoir, one of whom was closely associated with Arthur Markwart for more than forty years.

Mr. Markwart was elected an Associate Member of the American Society of Civil Engineers on July 9, 1906, and a Member on January 18, 1916.

FREDERICK MEARS, M. Am. Soc. C. E.[1]

DIED JANUARY 11, 1939

Frederick Mears, Colonel, United States Army (*Retired*), military and civil engineer, was born at Fort Omaha, Nebr., on May 25, 1878. He was the son of Lieut. Col. Frederick Mears, U. S. Army, a veteran of the Civil War who held a distinguished service record, and Elizabeth (McFarland) Mears.

---

[1] Memoir prepared by Ralph Budd, M. Am. Soc. C. E., and R. C. Jamieson, Esq.

He received his education in the public schools of New York, N. Y., and Spokane, Wash., and at Shattuck Military Academy, in Faribault, Minn., from which he was graduated in 1897. He was a distinguished graduate of the U. S. Infantry and Cavalry School, in 1904, and of the U. S. Staff College, in 1905, at Fort Leavenworth, Kans.

Colonel Mears' life and work reflected a unique blending of his military interests and his natural love of engineering construction. His boyhood surroundings of army life implanted in him a loyalty to the service, and his early association with John F. Stevens, Past-President and Hon. M. Am. Soc. C. E., then chief engineer of the Great Northern Railway Company, whose home young Mears often visited, aroused his interest in railroad construction. This twofold interest and double training undoubtedly made possible his engineering assignments and contributed to his success in accomplishing them.

Mr. Stevens gave young Frederick Mears his first railroad job after his graduation from the Shattuck Military Academy in the same class with Mr. Stevens' son, Donald. Mr. Mears went to the Fergus Falls Division of the Great Northern Railway as chainman and in two years worked up through the grades of rodman, levelman, and transitman to resident engineer of the Kootenai Valley, Bedlington and Nelson Railroad (a Great Northern subsidiary) in Northern Idaho and British Columbia.

The Spanish War led to his enlistment in the U. S. Army in 1899, and he was sent to the Philippine Islands during the Insurrection. He was commissioned Second Lieutenant in July, 1901, and continued his service with the 5th Cavalry at San Isidro, Luzon, P. I., for another two years.

After leaving the Army Service Schools at Fort Leavenworth, he held the position of resident engineer on construction of the Little Rock Southern Railroad at Fordyce, Ark., from July to October, 1905.

Army orders then transferred him for a short time to Fort Huachuca, Ariz., and back again to Fort Leavenworth to serve as aide-de-camp to Gen. J. Franklin Bell. He continued to fill this assignment until General Bell's appointment as the first chief of staff of the Army.

In 1906, at the request of Mr. Stevens, then chairman and chief engineer of the Isthmian Canal Commission, Lieutenant Mears was detailed as track foreman in Culebra Cut. When the relocation of the Panama Railroad was undertaken, he was assigned to that by Mr. Stevens and continued the work under the late George W. Goethals,[2] M. Am. Soc. C. E., Colonel, Corps of Engineers, U. S. Army. The work was under direct supervision of Ralph Budd and, in 1909, following Mr. Budd's resignation as chief engineer of the Panama Railroad, Lieutenant Mears was appointed to succeed him. It was during those years of service together in the Canal Zone that a professional and personal friendship that was never broken was formed between Mr. Budd and Lieutenant Mears.

As chief engineer, Lieutenant Mears also had charge of the design and construction of the reinforced concrete terminal docks at Cristobal and of a small boat landing at Gatun, and the construction of the New Washington Hotel on Colon Beach. He also made the survey for the Panama-David Railroad for the Panama Government—350 miles of line in the western part of the republic.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1813.

In 1913 he was appointed general superintendent and chief engineer of the Panama Railroad and Steamship Lines, having entire charge of the operation and maintenance of the railroad and of affairs pertaining to the steamship line on the Isthmus of Panama.

When the Alaskan Engineering Commission for the location and construction of a government railroad in Alaska was created by Congress, Lieutenant Mears was appointed a member on the recommendation of Colonel Goethals. He left the Isthmus of Panama early in 1914, and, after a conference with Secretary of the Interior Lane and the other members of the Commission in Washington, sailed on June 6 for Alaska. The summer of that year was spent in preliminary surveys to determine the best route from an ice-free port to the interior of the Territory. Lieutenant Mears made a daring and hazardous reconnaissance with one man and a pack train from Ship Creek to Fairbanks.

His field notes of those weeks, from June 18 to August 6, 1914, are an exciting day-by-day story of the conquest of 360 miles of wilderness northward from Cook Inlet through Broad Pass to the Tanana River. The regular trains rolling smoothly over the same country today give little indication of the difficulties of that trip. Sucking swamps, swollen rivers crossed on improvised log rafts, struggling horses rolling their packs and riders into the current, miles of cutting trail, shortage of rations, vicious mosquitos, and bruises, sprains, and cuts sewed up with common needle and thread were some of the hardships which Lieutenant Mears and his guide, Jim Wilson, encountered. Their arrival in Fairbanks was made memorable by the news that Great Britain had entered the World War.

The route first covered thus was recommended by the Commission, approved by the Secretary of the Interior, and construction started in the spring of 1915. Commission headquarters were established at the new town of Anchorage and Lieutenant Mears was assigned to that section of the work.

By the time the United States had entered the war, he had passed through the grades of Captain and Major in the regular Army. In January, 1918, after insistent application for active service, he was commissioned Colonel of the 31st Railway Engineers and returned to the United States to recruit the regiment. He made a tour of the training camps and selected twelve hundred experienced railroad men. They sailed for France on June 6 and rendered distinguished service on the French railroads for a year.

Colonel Mears served under the late W. W. Atterbury,[3] M. Am. Soc. C. E., Brigadier-General, U. S. Army, as assistant general manager and then as general manager of transportation at Tours, France, until May, 1919. Subsequently, he received the Distinguished Service Medal with the following citation:

> "For exceptionally meritorious and distinguished services. He served with distinction as Commanding Officer of the 31st Railway Engineers,

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1518.

> and later, as Assistant General Manager and General Manager, Railway Department, Transportation Corps. Due to his remarkable executive ability and skill as an organizer, the railways of the American Expeditionary Forces were operated with rare success and the huge transportation problem involving the carrying of tremendous quantities of supplies from the base ports to the fronts, was satisfactorily solved."

Colonel Mears was also awarded the Grand Cross of the French Legion of Honor, personally conferred upon him by Maréchal Pétain of the French Army.

Secretary Lane recalled Colonel Mears to the Alaska Railroad in May, 1919, and appointed him chairman of the commission in full charge of the work. He remained until the completion of the railroad in 1923.

When President Harding drove the golden spike in the Tanana River Bridge on July 15, 1923, Secretary of the Interior Hubert Work said of Colonel Mears, in part:

> "It has been said that every great achievement is but the shadow of a man. If so, it must in justice be said that the Alaska Railroad is the shadow of an intrepid builder, once a Lieutenant of Cavalry, later a Colonel of Engineers overseas, whose construction, like his character and conception of service, was without flaw. This great builder, clearly, has woven himself into the fabric of this railroad and enshrined in the hearts of the Alaska people, the name of Frederick Mears. Fifty-six millions of dollars were expended by this trusted servant of a generous government, in a wild country, with little supervision, but without avoidable error."

The golden spike was marked with his name and presented to Colonel Mears by the citizens of Anchorage. It remains a cherished possession of his family.

Upon completion of the Alaska work in 1923, Colonel Mears retired from the Army and accepted an appointment as chief engineer of the St. Paul (Minn.) Union Depot Company, succeeding W. C. Armstrong,[4] M. Am. Soc. C. E., who died June 12, 1923. The completion of the modern passenger station and accompanying track layout, which are owned and used by the nine roads entering St. Paul, was accomplished in less than the scheduled time, and in a highly satisfactory manner.

For some years the Great Northern Railway Company had been exploring the possibilities for improving its route across the Cascade Mountains. It had become apparent that some 20 miles of line revision, as well as a long tunnel, would be necessary to provide the same general character of railroad that prevailed elsewhere on the Great Northern main line. It was decided to electrify the entire Cascade Mountain section between Appleyard [Wenatchee] and Skykomish, Wash. (73 miles). The work to be done was in precipitous mountain terrain, and the experience and skill which Colonel Mears possessed to a marked degree fitted him peculiarly for this undertaking. He succeeded O. S. Bowen, M. Am. Soc. C. E., as assistant chief engineer in charge of Lines West, with headquarters at Seattle, Wash., in 1925. (It should be stated here that Mr. Bowen was thoroughly qualified in every way and that his replacement was because of severe arthritis, which necessitated a change in climate, and accordingly he was transferred to St. Paul.) Colonel Mears conducted the investigation for the new route across the Cascade Mountains with great thoroughness, and, late in November, 1926, the work on the 8-mile Cascade Tunnel was begun. The tunnel and the Chumstick Line on the east slope were completed and opened for traffic in January, 1929, establishing a new record for tunnel construction.

---

[4] For memoir, see *Transactions*, Vol. LXXXVII (1924), p. 1305.

In many ways, and possibly in every way, this, more than any other single project, should stand as a monument to Colonel Mears' engineering ability. It has been so thoroughly described by him[5] that it is not necessary to dwell upon details. The 8-mile tunnel tangent was extended over steep mountain sides more than 3,000 ft above the tunnel grade, and work was started at both ends, as well as in both directions from a shaft. Yet when the bore was holed through the alinement was perfect to within a few inches. Colonel Mears personally supervised the engineering work on this great project and deserves the credit for its successful execution. Of course, during his entire service as assistant chief engineer, from 1925 to his death in 1939, considerable improvement and replacement work was being done. The largest railroad extension during that period was the Great Northern Railway from Bend, Ore., to Bieber, Calif., a distance of 235 miles. It involved 160 miles of construction, which was done under Colonel Mears' supervision and completed in 1931.

In acknowledging for the War Department the report of Colonel Mears' death, Gen. Malin Craig, chief of staff of the U. S. Army, and a personal friend, said:

> "Colonel Mears was an officer of fine professional qualifications and attainments, with an exceptional knowledge of railroad and engineering construction, and was at all times found equal to the important and responsible positions in which he was placed during his many years of loyal and efficient service."

As an engineer and executive, Colonel Mears always had a broad view of "the job" and allowed nothing to interfere with it. He often exacted hard service of the men under him, but was so reasonable and kind that he never incurred their resentment.

Throughout his life Frederick Mears stood for the highest and finest in human relationship. He was known first and foremost for fairness and justice in all his dealings, and then for the dignity and graciousness of his quiet personality. The power of his splendid mind, his entire lack of egotism, his absolute honesty of thought and purpose, and his real kindliness and tolerance never failed in their effect upon those with whom he worked or played. A quiet sense of fun shone through his apparent seriousness to endear him to all who really knew him. "He could walk with Kings, nor lose the common touch."

He loved the outdoors with the real simplicity of those who spend most of their lives in the open and who accept and enjoy naturally its treasures and pleasures. He hunted and fished with great enthusiasm and had some fine specimens to show for his skill. Photography was one of his life-long hobbies, and, because of his meticulous precision and his skillful use of light meters and range finders, he has left an excellent picture record of his personal and professional life.

---

[5] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 926.

Perhaps nearest his heart were his books. They were his only extravagance and almost his closest friends. He read history and biography with an atlas at his elbow and found consolation for the trouble of modern society in contemplating those of ages past.

Ever alert to the developments of his profession, during July, 1937, he made a detailed survey and report of the snow-retard work near the Loetchberg Tunnel on the Bernese Alps Railway in Switzerland and of that on the Austrian State Railway near Innsbruck, Austria. He personally scaled the mountain tops at these two sites and took many pictures with which he illustrated his report to the chief engineer of the Great Northern Railway. He received the utmost courtesy and cooperation from the French, Swiss, and Austrian engineers and had much pleasure in the new experience. The report was his last outstanding contribution to engineering.

On April 6, 1907, Frederick Mears, then a Lieutenant, was married to Jennie Wainwright, daughter of the late Maj. R. P. Page Wainwright, U. S. Army. Two children, Josephine Wainwright and Elizabeth McFarland, were born to them in the Canal Zone, and two younger children, Frederick, Jr., and Helen Rogers, were born in Alaska. Helen died in 1929.

Colonel Mears was elected an Associate Member of the American Society of Civil Engineers on February 1, 1910, and a Member on September 2, 1914.

SAMUEL PHILLIPS MITCHELL, M. Am. Soc. C. E.[1]

DIED FEBRUARY 11, 1940

Samuel Phillips Mitchell was born on June 10, 1864, in Richmond, Va., the son of Samuel Phillips and Mary (Fry) Mitchell.

Prior to 1900, the art of designing and manufacturing metal bridges in the United States, as based on the historic treatise[2] of the late Squire Whipple,[3] Hon. M. Am. Soc. C. E., had been marked by a high degree of success. The advance in competent, daring design and economical shop processes had been rapid. However, the methods of building the bridge in the field, although usually carried out with great skill, were generally performed with a very limited amount of engineering direction and in the same manner practised for many years.

First, a temporary timber falsework carrying a movable timber hoisting apparatus, called a traveler, was built. Then the bridge was erected on the falsework, and lastly the traveler and the falsework were removed. When spans were short, the timber falsework was minimized or, if possible, omitted. Large quantities of timber were required and the supply of long-leaf pine, frequently used, was diminishing rapidly and increasing in cost almost as rapidly as it diminished. The timber structures needed many men for construction and operation; and although the field workmen of the time were perhaps unequaled by their successors, still it scarcely can be said that field methods were on a par with those of the shop and office.

---

[1] Memoir prepared by R. Murray, M. Am. Soc. C. E.

[2] "A Work Upon Bridge Building, Consisting of Two Essays, the One Elementary and General, the Other Giving Original Plans and Practical Details for Iron and Wooden Bridges," by Squire Whipple; H. H. Curtiss, Utica, N. Y.

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. XXXVI, December, 1896, p. 527.

The year 1900 saw the amalgamation of all except a few of the principal bridge companies into one company. This company was officered by a group selected from the staffs of the constituent companies, resulting in a body of men of exceptional ability. The engineer placed in charge of the field work was Samuel Phillips Mitchell.

Mr. Mitchell had entered railroad work, in 1883, for the Danville and New River Railroad Company and the Baltimore and Ohio Railroad Company. His work for the Baltimore and Ohio Railroad Company covered the construction of its extension from Baltimore to Philadelphia, and in the large bridges over the Susquehanna and Schuylkill rivers he found his métier. When his work was completed in 1887, he secured employment with the Edgemoor Bridge Works of Wilmington, Del., where his advancement was rapid. He became manager of the company, in charge of all its operations, in 1896. His service with Edgemoor was marked by the number of large bridges built over many of the principal rivers of the United States. It was found that Edgemoor's competitors might equal or perhaps even surpass in design or manufacture; but few could match the economy and speed of the field organization. Therefore, when Edgemoor joined the amalgamation, Mr. Mitchell was the logical choice to take charge of field operations. It is not too much to say that in this period (1900–1908) as chief engineer of the American Bridge Company of New York he revolutionized field methods of bridge building in the United States.

The use of timber was minimized, and wooden travelers were discarded and replaced by several types of heavy bridge erecting cars designed under his supervision for repeated use for various kinds of bridges. When these were not suitable, steel travelers capable of re-use and locomotive cranes were used. Manila rope and wooden shell blocks were abandoned where possible, and replaced by wire rope and steel blocks. Hand riveting was abandoned and advanced power units were used. Limited engineering preparation and supervision of field work were replaced by general consideration and direction of nearly all work by engineers. In short, the field was brought into equality with the shop. The success of these methods is perhaps best shown by the fact that, although bridgeman's wages rose in this period from 30 cents an hour to 50 cents, the cost of bridge erection did not increase. For some types of work, it actually decreased.

In his relations with labor, Mr. Mitchell won the respect and loyalty of all who knew him. His decisions were firm, but based on sound judgment and justice. The national association of employers which dealt with field labor matters was headed by him as chairman of the Executive Committee from its inception until his death. When questions of wage increases arose, he was usually found on the side of the men, if conditions permitted it.

In 1908 Mr. Mitchell organized and headed the Seaboard Construction Company, formed to exploit the advanced methods of bridge erection instituted by him. During the next twenty-five years, under his direction, this company built several hundred bridges without mishap for many of the principal railroads of the East. Also, Mr. Mitchell organized and headed the American Equipment Company, which company is still engaged in the manufacture of bolts, nuts, and rivets.

His consulting practice began at this time and included many of the large bridges of the United States. Among the number, it is difficult to particularize; but perhaps the Sciotoville Bridge over the Ohio River for the Chesapeake and Ohio Railway Company and the Castleton Bridge over the Hudson River for the New York Central Railroad Company might be mentioned as classic examples of successive-step, heavy cantilever erection. As consulting engineer for the St. Lawrence Bridge Company, he supervised the field construction and brought to successful completion the great Quebec Bridge over the St. Lawrence River.

No account of Mr. Mitchell would be complete which did not include his interests outside his profession. From his French Huguenot forbears he inherited a feeling for art, and he was himself no mean water colorist. In his Edgemoor days it was not uncommon to find him hard at work in some sylvan spot with his easel and brushes. He enjoyed the theater and in his memories he treasured the great names of the past—Bernhardt, Terry, Mansfield, Irving, and Booth. His reputation in gastronomy was secure, and no one refused an invitation to one of Mitchell's dinners. For such an event no trouble was too great to take. The chef was courteously harried until he outdid himself, and the sommelier was persuaded to seek the special reserve. At his place in Germantown, Pa., where he lived for nearly forty years, he spent much time and money in the design and care of the formal garden which was his pride.

Mr. Mitchell was dignified and courteous, but taciturn. That he was modest in a deeply sincere sense is demonstrated by a circumstance affecting his application for a professional engineer's license in Pennsylvania. His statement of professional record was terse—it barely "hit the high spots." When he was asked to elaborate, somewhat, to fill the standard needs, he supplied a record that was several pages long. This file in the archives of the Pennsylvania State Board of Registration is a most valuable biographical document.

The friendships he made were deep and warm, but not many. Those who knew him best will remember him in his characteristic pose, seated at a desk, meticulously groomed, with a rosebud in his lapel, a cigarette in one hand, while he tugged at his little red beard with the other—all the time carefully and thoroughly mentally analyzing the matter before him. His interest in the technical advancement of his profession was great and was shown clearly by his disposition of his residuary estate which he divided between the institution which he attended—the University of Virginia—and that which his son attended—the University of Pennsylvania, at West Philadelphia, Pa.

He was married early in life (February 8, 1888) to Miriam Bond, who, with their only son, Donald, survives him.

His clubs were the Racquet Club, Salmagundi Club, Engineers' Club of Philadelphia, Engineers' Club of New York, and the Wilmington Club; he was also a member of the Engineering Institute of Canada.

Mr. Mitchell was elected a Member of the American Society of Civil Engineers on April 1, 1903.

CHARLES NICHOLAS MONSARRAT, M. Am. Soc. C. E.[1]

Died March 1, 1940

Charles Nicholas Monsarrat was born in Montreal, Quebec, Canada, on July 2, 1871, the son of the late Mark R. and Mary E. G. Monsarrat. He traced his ancestry back through several generations to the north of Ireland where his forbears settled as Spanish Huguenots fleeing from persecution.

As a youth, in 1890, he joined the engineering staff of the then young and vigorous Canadian Pacific Railway Company, and through the usual channels of those days, namely, rodman, chainman, transitman, and draftsman, passed into the office of the chief engineer where he rose by 1902 to the responsible position of engineer of bridges. In this capacity he had charge of the inspection and maintenance of all bridge structures on the system whether timber, concrete, or steel, and in addition he and his staff did the office work incident to the design of new construction and the supervision of erection in the field. He occupied this office until 1911 and devoted his attention to many major projects of the Canadian Pacific Railway during this period of wide expansion. Among these, the most notable is perhaps the Belly River Viaduct, near Lethbridge, Alberta, which is a steel structure more than 300 ft high and a mile long. Other important structures in the west, which were built under Mr. Monsarrat's direction, were the high-level bridge in Edmonton, Alberta, a combined railway and highway structure over the North Saskatchewan River, and the original cantilever bridge over the Fraser River below Lytton in British Columbia. It was during his régime as engineer of bridges that the reconstruction of the famous Lachine Bridge over the St. Lawrence near Montreal was undertaken—the four-span continuous structure designed in 1885 by the late C. Shaler Smith,[2] M. Am. Soc. C. E., was replaced by two independent single-track structures built side by side on common piers to constitute a double-track crossing 3,659 ft long. Before this work had been completed, however, Mr. Monsarrat was appointed by the Department of Railways and Canals to succeed the late H. E. Vautelet as chairman and chief engineer of the Quebec Bridge Board, which Board had been set up by the Dominion Government to undertake the task of designing and supervising the construction of a double-track railway bridge over the St. Lawrence, near Quebec, to carry the National Transcontinental Railway, as it was then called. The original Board of Engineers had been appointed in 1908 following the Report of the Special Commission regarding the 1907 catastrophe, but upon the receipt of tenders preparatory to the award of contracts, the late Mr. Vautelet, who previously had also been engineer of bridges for the Canadian Pacific Railway Company, resigned office.

---

[1] Memoir prepared by P. L. Pratley, Esq., Montreal, Que., Canada.

[2] For memoir, see *Proceedings*, Am. Soc. C. E., Vol. XIII, August, 1887, p. 105.

Several years were required to build the deep-water granite-faced piers and to fabricate and erect this great cantilever span which still retains premier place in its own class of structure; and upon its completion, the services of Mr. Monsarrat were retained by the Department of Railways and Canals as consulting engineer, he and selected members of his staff being moved to Ottawa, Ontario. In 1920, when the Dominion Government decided to take over the Grand Trunk Railway Company, the Department set up a special staff in Montreal to undertake the investigations which were a necessary preliminary to arbitration proceedings, and Mr. Monsarrat was requested to recommend a bridge engineer and to supervise the organization of a bridge inspection office for the examination and valuation of all the bridges on the Grand Trunk System and its subsidiaries. For this appointment he recommended and secured the writer, who was then designing engineer of the Dominion Bridge Company and who had served several years as assistant engineer of design on the Quebec Bridge Board under Mr. Vautelet and later as engineer in charge of design for the St. Lawrence Bridge Company, the successful tenderers for the superstructure. Mr. Monsarrat, although stationed in Ottawa, undertook to visit Montreal weekly during the preparation of the inspection reports, valuation sheets, and other data, in the expectation of giving expert evidence at the sitting of the Arbitration Court. However, the decision of the Court was reached on financial grounds without the presentation of detailed technical evidence, and in due time the Canadian National Railways system came into being. The office of consulting engineer to the department was abolished and Mr. Monsarrat was appointed to the Operating Department of the new organization as consulting engineer on bridges, his staff in Ottawa being absorbed into other divisions of the department. As only part of his time was required by the Canadian National Railways, he and Mr. Pratley formed a professional partnership and entered into private practice as consulting civil engineers in April, 1921.

This partnership continued until the death of Mr. Monsarrat and was productive of much important engineering work, largely in the field of major bridge projects. Among the more outstanding contracts on which they were engaged as consulting, designing, and supervising engineers are the Montreal Harbour Bridge (Jacques Cartier), 1924–1931; the reconstruction of the Second Narrows Bridge in Vancouver, 1933–1934; the suspension bridge at the Isle of Orleans near Quebec, 1933–1935; and the Lions' Gate Bridge over the First Narrows at Vancouver, 1933–1939. They were engaged as consulting engineers on design to the general contractors for the Detroit-Ambassador Bridge, 1928–1929; as Canadian associate engineers on the International structures at Sarnia, Canada, and Port Huron, Mich., 1928–1938, and the Thousand Islands, 1933–1938; and as engineering consultants on a variety of work in the Niagara District for the International Railway Company of Buffalo, N. Y.

In 1929 this partnership became associated as structural engineers in a greater partnership bearing the name of Terminal Architects and Engineers, and included architects and service engineers to develop a professional contract for the design, detail drawing, and supervision during construction of the proposed new passenger terminal for the Canadian National Railways, at the Dorchester Street site in Montreal. This undertaking was part of a very comprehensive railway project (the estimates for which amounted to $50,000,000), and involved extensive relocation of trackage, expansion of facilities, new offices, and a large program of city planning to absorb the numerous new bridges and viaducts necessary for the establishment of a modern uptown railway station. Being subject to political control, this entire scheme was suspended in 1931 by the new administration coming into office after the federal election, and only in 1939 was work resumed at the site. The project was considerably reduced in magnitude, the engineering contract was canceled, and the technical work absorbed by the railway's own staffs.

Mr. Monsarrat was always interested in military affairs and in his early life served with the Victoria Rifles of Canada, one of the oldest militia units in the Montreal District. In 1905 he took out a commission in the Royal Highlanders and rose through all the intervening ranks to the command of the regiment as Lieutenant-Colonel in June, 1915. At the end of the World War in 1918 he retired to the reserve of officers, from which he was released upon reaching the age limit of liability to recall for service.

Colonel Monsarrat was a member of the Engineering Institute of Canada, upon whose Council he served during the years 1910, 1912, 1913, and 1914, and of which he was Vice-President during 1917. He was a charter member of the Corporation of Professional Engineers of the Province of Quebec, and served on its Council during the period 1921–1937, being vice-president during 1926, 1927, and 1933. For many years he was a member of the American Railway Engineering Association.

In recent years he gave freely of his time and effort to the financial and building committees of the Anglican Church of St. James the Apostle in Montreal, where his professional advice was highly appreciated. For many years he was a director of the Canada Foundries and Forgings Limited, whose principal plants are in Welland and Brockville, Ontario. His recreation was golf, but he also enjoyed the pleasures of touring by automobile. He was of a most kindly and companionable disposition, was abundantly endowed with the saving grace of humor, and brought to bear on all problems a wealth of sound judgment almost instinctive in its effectiveness.

He was married on February 9, 1898, to Mary Alice Foster in Montreal. He is survived by his widow, one son and one daughter, and three grandsons.

Colonel Monsarrat was elected a Member of the American Society of Civil Engineers on March 4, 1913.

ASA HALL MORRILL, M. Am. Soc. C. E.[1]

Died December 20, 1938

Asa Hall Morrill was born in the Penacook Section of the City of Concord, N. H., on October 7, 1870, the son of George S. and Clara A. (Moody) Morrill. Following his education in the public schools of Concord, he entered the Massachusetts Institute of Technology, at Boston, Mass., from which he was graduated in 1892 with the degree of Bachelor of Science.

Asa Morrill was reared in an atmosphere of engineering. For thirty-eight years his father, the late George Morrill, M. Am. Soc. C. E., was actively engaged in engineering, first as chief engineer of the Old Colony Railroad Company and later as Division Engineer of the New York, New Haven and Hartford Railroad Company upon the consolidation of the Old Colony with the New Haven Road. Asa Morrill's brother, Harley W. Morrill, also an engineer, attended the Massachusetts Institute of Technology for about three years as a member of the class of 1893, and for ten years thereafter was associated with the New York, New Haven and Hartford Railroad Company as an engineer in maintenance of way service.

As a boy, Asa Morrill, in his spare time, found pleasure, interest, and profit in the local industries and about the railroad rather than in sports or athletics. He took great delight in relating the early experiences and incidents of his boyhood jobs in the print shop, the textile mill, the wood working shop, but more particularly at the railroad station. He considered the practical and diversified experience thus obtained as a valuable part of his education and an important and helpful asset in later life.

Railroading fascinated him, and as a son of a railway chief engineer he was destined to follow it as a career with outstanding success. Upon graduation from college in June, 1892, he entered railroad service as an assistant engineer with the Buffalo, Rochester and Pittsburgh Railroad Company, continuing until August, 1892, when he became assistant engineer of the Old Colony Railroad, later absorbed as a part of the New York, New Haven and Hartford Railroad Company system. From August, 1892, until November, 1912, he remained in the service of the Old Colony and New York, New Haven and Hartford Roads except for a short period, April, 1898, to August, 1898, when he was engaged in railroad contracting service as a superintendent for a construction company. His service with the Old Colony and New Haven railroads included positions of assistant engineer, draftsman, assistant roadmaster, and assistant engineer of construction. He entered the service of the Boston and Maine Railroad in November, 1912, as division engineer of construction on grade-crossing elimination work and he continued in the service of that road through January, 1913.

On February 1, 1913, he was appointed engineer of construction and valuation engineer of the Maine Central Railroad and Portland Terminal companies, and in April, 1928, he was appointed chief engineer of the same roads. On April 15, 1933, he was made assistant chief engineer of the Boston and Maine Railroad, the Maine Central Railroad Company, and the Portland Terminal Company. He served as acting chief engineer of the three roads from April 13, 1936, until July 13, 1936, when he was appointed chief engineer. He served in this capacity until his death.

---

[1] Memoir prepared by W. F. Cummings, Chief Engineer, Boston & Maine Railroad—Maine Central Railroad Co., Boston, Mass.

During his service with the Old Colony and New Haven roads he was in direct charge of four-track improvements and preparation of plans for track elevation through Brockton, Mass. As assistant roadmaster he was in general charge of construction and maintenance forces on one hundred and fifty miles of road including the Boston Freight Terminals. As assistant engineer of construction he had direct charge of preparation of all constructions plans (except steel bridges) for elimination of grade crossings in Boston, New Bedford, Hyde Park, and Worcester, in Massachusetts. In addition, he was in charge of surveys and the preparation of preliminary plans for extensive and varied construction and improvements.

On the Maine Central and Portland Terminal companies he was in charge of engineering, valuation, construction, and maintenance. Outstanding among his accomplishments on these roads was the building of Rigby Yard in Portland, Me., and the construction of extensive wharf and dock facilities also at Portland including modern and efficient equipment for speedy and economical handling of bulk and general cargoes. Passenger station facilities at Ellsworth, Me., were designed and constructed under his direction.

On the Boston and Maine Railroad his initial undertaking as chief engineer was to complete the restoration of flood-damaged lines following the New England floods in March, 1936, which caused widespread destruction to the property of the railroad. By a rather strange coincidence his final accomplishment as chief engineer prior to his death was a similar undertaking following the New England floods and hurricane of September, 1938, which affected approximately 1,000 miles of the Boston and Maine Railroad and caused extensive and severe damage at more than three hundred different locations.

Passenger station facilities at Cambridge, Mass., and White River Junction, Vt., were designed and constructed under his direction.

Asa Morrill, widely known as " Ace," was a natural seeker of facts and a keen analyst. He was intuitive, ingenious, and richly endowed with common sense and good judgment. His natural talents, together with his education and training and an unusually broad engineering and construction experience, gained for him an enviable reputation as a competent and successful engineer. He was a vigorous man possessed of poise and the power of decision. His opinions were valued and respected. He was a man of integrity and devotion to duty, charitable and friendly. He was widely loved and respected and his friends were legion.

He was a member of the American Railway Engineering Association, Terminal Engineers Association, the Maine Association of Engineers, the Portland Club, the Lions Club and Prouts Neck Country Club of Portland,

and the New England Railroad Club, Algonquin Club, and Engineers Club of Boston.

He also served as chairman of the New England Committee on Marine Piling Investigation from 1935 to 1938 and the Valuation Committee of the Maine Central and Portland Terminal companies from 1928 to 1933.

He was a prodigious reader, and his recreations included photography, horticulture, and the building of ship models.

He was married to Elizabeth E. Norris at Dedham, Mass., on June 2, 1902. He is survived by his widow, a daughter, Marjorie N. Morrill, and a brother, Harley W. Morrill.

Mr. Morrill was elected a Member of the American Society of Civil Engineers on May 3, 1910.

RALPH HADLOCK OBER, M. Am. Soc. C. E.[1]

DIED AUGUST 30, 1931

Ralph Hadlock Ober was born in Beverly, Mass., on May 20, 1871, a son of Andrew Kimball and Sarah A. (Hadlock) Ober, and a descendant of an old and prominent Colonial family established in America during the earliest period of Colonial settlement. Some of the original leaders of the Massachusetts Bay Colony are included in the direct family line.

Mr. Ober received his education in the public schools of his birthplace, at Beverly Academy, and at Massachusetts Institute of Technology, at Boston, Mass. He later completed a course in law and was admitted to the bar in the State of Washington, although he never practiced that profession.

In 1892 Mr. Ober served successively as chainman, rodman, instrumentman, and inspector on the location and construction of the Adirondack and St. Lawrence Railroad. In 1893 he was engaged in general surveying work in Beverly, and at the end of that year he transferred his activities to the Pacific Northwest. In 1894 he served as instrumentman on land surveys and as special examiner of surveys for the U. S. Indian Bureau, in the State of Washington. In 1895 he was employed as instrumentman and inspector on the construction of a storage dam at Cedar Lake, Washington. During 1896 and 1897 he made surveys of the islands in the Gulf of Georgia, Washington, for the U. S. Surveyor General. Also, during those two years, as well as during the years 1905 and 1906, as U. S. Deputy Surveyor, he made extensive land surveys in the State of Washington.

For a part of the year 1896, and from 1897 to 1905, he was employed as civilian engineer with the Corps of Engineers, U. S. Army, in the State of Washington. His assignments during that period included, successively: Rodman and instrumentman on general surveys; in charge of river surveys and of preparing maps and reports; on construction of the fortifications at

---

[1] Memoir prepared by Joseph Jacobs and O. A. Piper, Members, Am. Soc. C. E.

Forts Casey and Worden; junior engineer and superintendent of construction of gun and mortar batteries, and of other fortification works at Forts Worden and Flagler; in charge of Drafting Department, making detailed plans and estimates for rapid fire batteries and of central electric power buildings and plants at Forts Worden, Casey, and Flagler; and assistant engineer in charge of fortification work at Forts Worden and Flagler.

Leaving federal employment, Mr. Ober, in 1906, served as consultant for the Wenatchee High Line Canal Company in some of its irrigation development, was connected with the location of the Vancouver, Victoria and Eastern Railway in British Columbia, and was engineer in charge of substructure construction of an electric railway and highway bridge across the Columbia River at Wenatchee, Wash. During 1907 and 1908 he was resident engineer in charge of construction of the main line bridge across the Columbia River at Beverly, Wash., for the Chicago, Milwaukee and St. Paul Railway Company. He also served that company on a special engineering assignment in connection with important matters relating to terminal facilities at Seattle, Wash., Everett, Wash., and other points on the western end of its railway system.

From the latter part of 1908 until 1914 Mr. Ober was in the employ of the City of Seattle, serving as court engineer and as assistant city engineer until 1911. In these capacities he had charge of much important work, including an investigation of the Cedar River Watershed and its reforestation for city water supply purposes, and he represented the city engineer in the condemnation proceedings to acquire control of the watershed. He also made an investigation, and prepared estimates and reports for an enlarged water supply system and for an additional hydroelectric plant for the city. In 1911 he was appointed superintendent of buildings and member of the Board of Public Works, and served as such for a period of three years.

Mr. Ober retired from the city's service in 1914 and thereafter, for a period of nearly five years, he was engaged in private practice as a consulting engineer in the City of Seattle, specializing largely in municipal and in river and harbor work. Following the entry of the United States into the World War, he enlisted in the Army, was commissioned a Captain in the 5th Engineers, and was stationed at Camp Humphreys, Virginia, where he remained until May, 1920. Among his other duties there he served as instructor in civil engineering, giving courses in roads and pavements, timber, steel, and masonry construction, etc. He received high praise as an instructor and upon his discharge from the Army was awarded the Victory Medal.

Following his discharge from war service Captain Ober again returned to the Corps of Engineers, U. S. Army, and for a period of three years had important supervisional assignments with channel rectification, dredging, and the construction of locks and dams along a 250-mile stretch of the Ohio River, with headquarters at Louisville, Ky. Following this service, Captain Ober returned to Seattle to resume his private practice and there, after the lapse of a year, he formed a partnership with Joseph Jacobs, M. Am. Soc. C. E., under the firm name of Jacobs and Ober, in the practice of consulting engineering. This very pleasant partnership continued until the passing of Captain Ober in 1931, and during its continuance the firm (or its individual members) was retained in connection with many important engineering projects. Among these were several federal and state irrigation enterprises—the Skagit River and Cedar River power investigations for the City of Seattle, the street and railway grade separation project for the City of Seattle, and the Lake Union Bridge project for the State of Washington. The Lake Union Bridge was an outstanding highway bridge project of the time. Captain Ober's work on the project was exceptionally skilful under trying requirements and contributed very largely to the success of the project.

He was an able engineer and a gentleman of quiet dignity and fine personality. His outstanding traits of character were his modesty, his uncompromising conscientiousness, his strict devotion to duty, and his capacity for detail thoroughness in all matters with which he concerned himself. He was a student of languages and had made himself quite proficient in Spanish, French, and Russian, particularly the latter. He was a lover of the outdoors, and he spent most of his holidays on fishing and hiking expeditions.

On May 30, 1903, Captain Ober was married, at Port Townsend, Wash., to Mattie Elizabeth Shattuck. She and their adopted daughter, Carol Evelyn, survive him. Besides more distant relatives, he leaves also a sister, Mrs. John P. Fay.

Captain Ober was a member and past vice-president of the Engineers Club of Seattle and of the Pacific Northwest Society of Engineers; an Associate Member of the American Institute of Electrical Engineers; and a member and past-president of the Seattle Local Section of the Society.

Captain Ober was elected a Member of the American Society of Civil Engineers on December 4, 1907.

CHARLES REAL OLBERG, M. Am. Soc. C. E.[1]

DIED APRIL 4, 1938

Charles Real Olberg was born on August 19, 1875, at St. Paul, Minn., his father, John G., having moved there from Norway in 1870; his mother, Ella C. (Lacker) Olberg, was a Virginian. When Mr. Olberg was five years old, his family moved to Washington, D. C., where he was educated in the public schools, Central High School, and Columbia University (later George Washington University). He was graduated in 1900 with the degree of Bachelor of Science in Civil Engineering. Later he took postgraduate work in mathematics and hydraulics at the University of California, at Berkeley, Calif.

Prior to entering college, Mr. Olberg obtained engineering experience as a rodman and instrumentman on surveys and construction of irrigation canals at Crow Indian Reservation in Montana, from June, 1894, to September, 1896. While in college he worked as a structural draftsman in the Supervising Architect's Office, in Washington, D. C., from September, 1896, to April, 1900, at which latter time he became an assistant hydrographer for the U. S. Geological Survey, in connection with irrigation investigations in Arizona. He held this position until June, 1902, when he entered the U. S. Reclamation Service, first as an assistant engineer, and then as engineer, on preliminary work in connection with the Roosevelt Project, in Arizona, and on construction of the Newlands (Nevada) Irrigation Project. In 1905 he became a structural engineer in the office of the Quartermaster General, U. S. Army, in Washington, D. C. While in this position Mr. Olberg was in charge of various structures being built for the army.

---

[1] Memoir prepared by John C. Hoyt, M. Am. Soc. C. E.

In July, 1907, he went to Los Angeles, Calif., where he became supervising engineer, District 4, U. S. Indian Office, in charge of investigations, reports, design, and installation of various irrigation works in Southern California and Arizona.

When the United States entered the World War, Mr. Olberg joined the U. S. Army in August, 1917, and was commissioned a Captain in the Army Engineer Corps. He was overseas from June 15, 1918, to August 12, 1919, in charge of construction and operation of machine shops at Engineer Depot, Base Section No. 2 (he reported for duty at Depot on November 8, 1918). During July and August, 1918, he commanded Company L, 116th Engineers. He attended the 3d Corps School, and Clamecy Bridge School, in Langres, France, during September and October, 1918. On August 29, 1919, he was honorably discharged from the Army, receiving the appointment of Major in the Engineering Section, Officers' Reserve Corps, on January 28, 1920. The commission expired on January 4, 1935.

Returning to the United States, Major Olberg took a position as assistant chief engineer, U. S. Indian Service, on construction and design of miscellaneous irrigation structures and projects, the most notable being the $12,000,000 Coolidge Dam on the Gila River, and the Roosevelt Dam on the Salt River, both in Arizona. The Coolidge Dam was one of his outstanding engineering works. The dam creates a reservoir of 1,250,000 acre-ft of storage capacity. It is of the multiple-dome type and contains many new and heretofore untried features. Major Olberg held this position for ten years (September, 1919, to September, 1929).

His next work was as a consulting engineer for the Russian Government on the design of dams and reclamation projects. These included the Mingichaur Project and various irrigation, hydroelectric, and drainage projects in Georgia (Russia), Armenia, and Azerbaijan. During this period he also served the countries of Peru, Argentina, and Mexico as consulting engineer on irrigation work.

Completing this work in February, 1933, Major Olberg returned to the United States, and from August 17, 1933, to January 15, 1935, he was engineer examiner for the Public Works Administration, after which he was engaged in consulting work and private hydraulic research, a subject in which he had always been especially interested. At the time of his death, he was consultant for the Resettlement Division of the Farm Security Administration, and was working on one of the administration's projects at Amarillo, Tex.

While with the U. S. Reclamation Service and U. S. Engineer Office, Major Olberg designed and had charge of construction of a large variety of irrigation works. He had the rare combination of being both highly theoretical in investigation and design, yet extremely practical in construction and operation. In addition to his regular work, he invented several devices which have extensive application and use in engineering activities.

Major Olberg was especially known for his kindness and helpfulness to all with whom he came in contact. He was never too busy to assist those who presented their problems to him, whether they were personal or technical. He was an Episcopalian and a Mason and a member of the Society of American Military Engineers, the Cosmos Club of Washington, D. C., University Club of Los Angeles, Arizona Club of Phoenix, Ariz., the Kappa Sigma Fraternity, the American Legion, the Concrete Institute of America, and the Military Order of the World War.

He was married to Eloise M. Oliver, of Oswego, N. Y., on February 3, 1904. She died on October 23, 1921. In 1927 he was married to Mary M. Bell, of San Gabriel, Calif., who survives him. He is also survived by two sisters, Mrs. Camille M. Craft and Mrs. Norma Forsyth.

Major Olberg was elected an Associate Member of the American Society of Civil Engineers on May 7, 1902, and a Member on December 4, 1922.

IRWIN SELDEN OSBORN, M. Am. Soc. C. E.[1]

Died November 2, 1935

Irwin Selden Osborn was born on January 24, 1878, in what later was known as Bay Village, Cuyahoga County, Ohio, 12 miles west of Cleveland, the son of Reuben and Eunice (Chadwick) Osborn.

His mother, at the age of 90 yr, is still living in the home on the south shore of Lake Erie, built by his great-grandfather, Reuben Osborn, when he and his wife, Sarah, each took up claims from the Western Reserve Land Company in 1811. The Osborns were the first white settlers to spend a winter west of Cleveland.

Mr. Osborn attended Oberlin Academy, at Oberlin, Ohio, for four years, stopping one year to teach in a public school at Avon Lake, Ohio. He entered Oberlin College at Oberlin, where he spent one year, during which time he played right half-back on the Varsity football team. After his Freshman year at Oberlin, he became interested in sanitary engineering and enrolled at Purdue University, at Lafayette, Ind., as a Sophomore. He was graduated from Purdue in 1904 with a degree of Bachelor of Science in Civil Engineering. In 1909, the University conferred on him the degree of Civil Engineer.

---

[1] Memoir prepared by a Committee of the Cleveland Section, consisting of James H. Herron and George B. Sowers, Members, Am. Soc. C. E.

Mr. Osborn played football throughout his college life and was Captain of the Purdue team in 1903, when sixteen of the squad were killed in a railroad train wreck.

His first engineering work was done in the summer of 1903, for Ritchie and Ruple, Engineers, of Cleveland, on the construction of a bridge at Painesville, Ohio, for the Painesville, Ashtabula and Eastern Electric Railroad Company, and doing some municipal work.

Upon his graduation from Purdue University, Mr. Osborn went to Toledo, Ohio, with the Edson Reduction Machinery Company, of Cleveland, to build and test a new garbage reduction plant for that city. Later, he became Chief Engineer of the Company and prepared plans for other garbage reduction plants.

In 1907, Mr. Osborn became associated with the Roberts and Abbot Company, of Cleveland, and was sent to Baltimore, Md., to take charge of building five miles, into Baltimore, of the Washington, Baltimore and Annapolis Railway. This road was largely elevated tracks with five bridges. Upon the completion of this work he returned to Cleveland as Engineer of Bay Village.

In September, 1908, he was appointed City Engineer of Oberlin, and served a short period, when he was appointed Consulting Engineer for Columbus, Ohio, on the model sanitary plants then being built there. While in the employ of the City of Columbus he designed and built a garbage reduction plant for that city which was a model for odor elimination.

The second plant of this character built by Mr. Osborn was in Philadelphia, Pa., and the third on Staten Island, New York, N. Y., for the Metropolitan By-Products Company of New York City.

Because of the successful operation of the Columbus plant, engineers came from many cities to visit it, including some from England, Germany, France, Wales, Japan, and South America. Among them was the Director of Public Health from Toronto, Ont., Canada, who engaged Mr. Osborn to come to Toronto after a trip abroad made with John Turney Fetherston, M. Am. Soc. C. E., of New York City. Mr. Osborn and Mr. Fetherston visited thirty cities in Germany, Belgium, Holland, France, England, Wales, and Scotland.

In Mr. Osborn's contract with the City of Toronto he retained the right of consulting work with other cities. These included New York City, Chicago, Ill., and Washington, D. C. Mr. Fetherston joined him in a report for Chicago the first year, and Mr. Osborn completed the report for Washington, D. C., the second year. These reports consisted of a survey of the cities with an analysis of quantity, quality, collection, and maintenance of wastes with completed plans for the building of the necessary plants and equipment. In Toronto, plans were completed for both reduction and incineration plants.

During the 1913 flood, in Ohio, Mr. Osborn was placed in charge of the flood emergency and relief work.

In the fall of 1915 he returned to Cleveland and with Mr. Virgil D. Allen organized the Allen-Osborn Company, Consulting Engineers, with offices in both New York City and Cleveland.

In October, 1917, Mr. Osborn was called to Washington, D. C., to take charge of a Department for the Conservation of Food Waste and to make a survey of the entire country under Herbert Hoover, Hon. M. Am. Soc. C. E., then Secretary of Commerce. After four months in the Department of Commerce, the late General George W. Goethals of the Quartermaster Department, United States Army, M. Am. Soc. C. E., asked for Mr. Osborn's release to do the same kind of work for the Quartermaster Department, at which time he received a commission as Major. Major Osborn was ordered overseas on July 1, 1918, but, later, was withheld for special work in the cantonments. He was honorably discharged from the Army and returned to his family and engineering office in Cleveland on January 25, 1919.

In 1922 he became Vice-President of the C. O. Bartlett and Snow Company, of Cleveland, in charge of a new Department for the design and construction of garbage and refuse disposal equipment and plants. Waste surveys were made in many cities; plants were designed, built, and operated in Asheville, N. C., Birmingham, Ala., New Orleans, La., New York City, Syracuse, N. Y., Rochester, N. Y., Montreal, Que., Canada, and Toledo, Philadelphia, and Toronto. He remained with this Company until his death.

Mr. Osborn specialized largely in the solution of municipal refuse problems and was known throughout the United States and Canada as an authority on the subject. His broad knowledge of, and experience in, the disposal of refuse was made available to public officials through his service on local committees and on committees of the engineering societies, in addition to his consulting services. He was never too busy to give a helping hand in the solution of a troublesome refuse disposal problem.

He was a member of the American Road Builder's Association, National Health Council, American Public Works Association, and the American Soy Bean Association. He was also a member of the Cleveland Engineering Association, and Sigma Alpha Epsilon Fraternity.

He was married on April 9, 1906, to Amy L. Reed, of Oberlin, Ohio, who, with two children, survives him.

Mr. Osborn was elected an Associate Member of the American Society of Civil Engineers on December 3, 1912; and a Member on January 18, 1916.

GUY PINNER, M. Am. Soc. C. E.[1]

Died June 25, 1939

Guy Pinner was born on June 7, 1888, in Elizabeth City, N. C., the son of John R. and Melissa (Brickhouse) Pinner. He received his early education in public and private schools, and college preparatory school. He was graduated in 1907 from North Carolina State College of Agriculture and Engineering with the degree of Bachelor of Science in Engineering. In 1912 he received the professional degree of Civil Engineer (C.E.) after five years of experience and a thesis on bridge design and erection.

---

[1] Memoir prepared by R. de C. Greene, Esq., New York, N. Y.

He began his engineering career in June, 1907, with the Phoenix Bridge Company at Phoenixville, Pa., as a draftsman. From 1909 to 1912 he covered detail designing, drawbridge machinery, and emergency dams for the Panama Canal, for the American Bridge Company at Edge Moor, Del., Pencoyd, Pa., Ambridge, Pa., and for Post and McCord in New York, N. Y.

From March, 1912, to June, 1914, he was Assistant Engineer to Herbert C. Keith, M. Am. Soc. C. E., consulting engineer of New York. Mr. Pinner was in charge of office and field work, estimating and checking bridges of steel, reinforced concrete, etc.

From June, 1914, to June, 1915, he organized and had charge of the Safety and Efficiency Engineering Department; and he also conducted contract bond investigations for underwriting, for the American Indemnity Company of Galveston, Tex. He was then asked by the company to take their General Agency in San Antonio, Tex., where he remained until March, 1916; but at that time he preferred to return to the direct engineering field.

From March, 1916, to June, 1918, he was bridge engineer for the Seaboard Airline Railway Company, at Norfolk, Va., in charge of maintenance and construction of all steel bridge structures, etc., for 3,500 miles of track. At the same time, as a member of the firm of Frink and Pinner, Construction Engineers, he designed and supervised construction of a large highway bridge near Camden, S. C., for Kershaw County, South Carolina.

In June, 1918, Mr. Pinner went to James Stewart and Company as engineer in charge of operations and construction at the Naval Operating Base in Norfolk. From June to September, 1921, he was in their New York Office as structural engineer in charge of engineering for piers, docks, buildings, etc. In August, 1921, he was made southern manager of Stewart and Company with headquarters at Norfolk, but before installation in office he was sent by the company to Colombia, South America, as construction engineer for the Andian National Corporation, to survey a harbor for a large oil terminal for shipping products of the International Petroleum Company. Following this inspection he was made chief engineer of the Andian National Company, with headquarters in New York City. Later he was manager in Colombia, where he remained until 1924, purchasing properties, operating the ocean terminal, and reconstructing and planning future developments.

From January, 1925, to October, 1929, he was with The Foundation Company in connection with foreign business; returning to Colombia again, he spent five or six months negotiating with the national government for railroad reconstruction contracts. This assignment was not concluded and in 1926 he returned again to Colombia, Panama, Costa Rica, Venezuela, and Curaçao in connection with new business. In 1927 he was in charge of Latin American work in the New York Office and then transferred to The Foundation Company, Foreign—and in March, 1928, he was elected to the board of directors and made vice-president of the company, in charge of the New York Office for European and Far Eastern affairs.

In 1929 Mr. Pinner resigned from The Foundation Company to become construction engineer for the American Cyanamid Company. In 1931 he was made chief engineer in charge of design and construction of plants for the making of fertilizer, chemicals, explosives, etc. He also held office in three Cyanamid subsidiaries.

He was an indefatigable worker and gave his personal attention to the details of every project, never passing a design until he had acquainted himself with all its features and thoroughly checked its soundness. He was gifted with a remarkable memory, a sound sense of economics, and excellent judgment.

A fine executive, he possessed a keen sense of humanity and justice, and was beloved by all his associates.

Mr. Pinner was a member of the American Railway Engineering Association, the Engineers Club, the Westchester Country Club, Rockefeller Center Luncheon Club, the Valhalla and Sound Beach Skeet Club, and Kappa Sigma Fraternity.

He was married on June 30, 1937, to Barbara Lawson, who survives him.

Mr. Pinner was elected an Associate Member of the American Society of Civil Engineers on November 12, 1913, and a Member on October 12, 1921.

T. FRANK QUILTY, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 16, 1939

T. Frank Quilty, known for forty years for his continuous pioneering in construction engineering, died September 16, 1939. His death occurred, after a brief illness, in the Sacred Heart Hospital, at Milwaukee, Wis.

Mr. Quilty was well known throughout the Middle West. During his entire life he was a believer in the new and progressive, whether in engineering or in technical problems of construction materials. This was the keystone of Mr. Quilty's life—a love of progress.

He was born in Chicago, Ill., on January 31, 1874, the son of Patrick Quilty and Johanna (O'Dea) Quilty. He was educated at St. Ignatius College, in Chicago. His father moved to a ranch at Spaulding, Nebr., and the boy took part not only in the herding of cattle but also in the Sioux War of 1891, at the battle of Wounded Knee, S. Dak. Frank Quilty gained here his life love of battling strenuously with nature. The one object of his vacations as a construction contractor was big game fishing in Florida, moose hunting in Canada, etc.

On his father's death the twenty-year-old Frank Quilty returned to Chicago and began work as a rodman at $1 a day. Then, by passing Civil Service examinations, he entered the Chicago City Hall in the Department of Engineers.

---

[1] Memoir prepared by Joan d'Arc Quilty, Naperville, Ill.

Working under the late John Ernst Ericson,[2] M. Am. Soc. C. E., Frank Quilty advanced rapidly. He was still in his twenties when he became assistant city engineer. Young Quilty was one of the principal supervisors of the gigantic tunnels under the city streets that made Chicago at that time the foremost city in the world in sanitary facilities.

In 1897 Frank Quilty entered private contracting. Specializing in railroad work, he successfully competed in bids for work on the Chicago and Alton Railroad, the Chicago and North Western Railway, Chicago and Eastern Illinois Railroad, and the Chicago, Burlington and Quincy Railroad. At that time he also had completed the Montrose Avenue Crib of Chicago, 5 miles out in Lake Michigan, to insure the city fresh water from depths of the lake. (Twenty years later it was still working "full blast.")

At the same time that he was bidding for the mammoth Kansas City, Mo., railroad terminal, he also bid for the hand of Margaret Lawler Martin, a young schoolteacher of Chicago. After his marriage (and completion of the Kansas City station in 1909), Frank Quilty further narrowed his field of railroad engineering construction by deciding to give his attention to the perfecting of the reinforced-concrete bridge. Some of his most noteworthy bridges at this date were the bridge over the great Rock River and the Okaw Viaduct.

Mr. Quilty forcibly promulgated the reinforced-concrete bridge at a time when iron bridges were just superseding the wooden bridge. He pointed out the strength, utility, and relative "agelessness" of concrete bridges (the beauty of the concrete arch against the green Illinois farm lands was not the least of considerations with him). The use of reinforced concrete in all forms of constructions was a pioneering battle in which Mr. Quilty fought continually. Many were the boards of state, city, and county commissioners he faced and convinced of his ideal—the ultimate in solid, ageless construction.

Mr. Quilty was much concerned at the entrance of America into the World War. When on New Year's Day, 1918, he received a telegram requesting him to accept a commission as Major of Engineers in the United States Army, he accepted; although it meant the breakup of his contracting firm and forfeiting of the railroad work, particularly large bids, from the Pennsylvania and Chicago and North Western railroad companies.

As a Major of Engineers he was commissioned to build a storage depot, comprising many square miles of reinforced concrete for central storage of military and munition materials away from coastal dangers, at Columbus, Ohio. Nine million dollars were allocated to him for this mammoth construction.

After the war Major Quilty was the owner and operator of stone quarries and gravel pits in northern Illinois. In his constant encouragement of the new advances in science, Major Quilty (among other pioneering trials which he fostered while president of the Superior Stone Company) conducted a series of experimental tests. These tests opened a new field for the producer of crushed stone and enriched the agriculture of Illinois. He proved that limestone was most efficacious when used by the farmer as a soil sweetener.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 1686.

Today it is interesting to see each stock truck, after delivering at the city cattle yards, load up with crushed limestone as it passes the quarries on its homeward trip.

In 1936, Major Quilty's interest in new fields of industry came to the fore in a number of chemical tests which he conducted personally in order to prove that sand is as binding as crushed stone or washed gravel in the mixing of concrete. By his championing of this new cause he raised sand from a nuisance material carried at a loss to a scarcity material of high value—this at the height of the 1937 depression!

For some years Major Quilty was a contributor not only to professional magazines but also to historical periodicals. At the time of his death he was completing an illustrated brochure of 50,000 words on the developments and needs of the sanitary districts of Chicago.

In addition to his membership in the Society, Major Quilty was a member of the Western Society of Civil Engineers, the Illinois Society of Civil Engineers, Chicago Engineers' Club, American Legion, Holy Name Society, Calvert Club, St. Ignatius Alumni, and Construction Division Association. He was a fourth-degree Knight of Columbus, and a Major of Engineers in the Reserve Officers of the United States Army. His interests and hobbies ranged from the study of natural history and anthropology to his pistol and gun collection and American history editions.

Major Quilty is survived by his widow, Margaret Quilty; two sons, T. Frank, Jr., and John Pershing; and two daughters, Joan and Margaret. The sons are following in their father's footsteps; both are deeply engrossed in civil engineering study and work.

Major Quilty was elected an Affiliate of the American Society of Civil Engineers on April 5, 1905, and a Member on September 5, 1911.

JOHN MATTHEW RAYBURN, M. Am. Soc. C. E.[1]

DIED JULY 20, 1939

Mr. Rayburn was born September 28, 1868, in Westmoreland County, Pennsylvania, and died July 20, 1939, after a severe illness of several months. His death, no doubt, was hastened by the death of his wife only twelve days before.

Mr. Rayburn's formal education ended with his graduation from the Central High School of Pittsburgh, Pa., a school with a proud record of offering to pupils of native ability, such as Mr. Rayburn, the fundamentals necessary for progression into the learned professions. Shortly thereafter he entered the service of McCully and Taylor, engineers in general practice in Pittsburgh. While with them he studied law and was nearly prepared for the rigid examination for admission to the Allegheny County (Pennsylvania) Bar when he was driven to a milder climate by impending tuberculosis.

---

[1] Memoir prepared by Samuel A. Taylor, M. Am. Soc. C. E., and W. E. Fohl, Esq.

Recovery from this malady was slow, but complete, and at thirty years of age he was able to discharge, successfully, the duties of chief engineer in the construction of the Parral and Durango Railroad in Old Mexico.

Upon his return from this engagement he was employed by the late Selwyn M. Taylor, M. Am. Soc. C. E., whose tragic death in the Harwick Mine disaster is recorded in the *Transactions* of the Society.[2] At the time of Mr. Taylor's death Mr. Rayburn was one of his most valued assistants, and already had achieved an enviable reputation by reason of his important part in the design and construction of the high-grade mining plants of the Eureka Fuel Company and the Pittsburgh Terminal Railroad and Coal Company, among others, in western Pennsylvania.

Immediately after Mr. Taylor's death Mr. Rayburn organized his own successful business which was taken over by his son and three trusted employees who helped him until his death.

A description of his professional activities from this time on, in any detail, would require a volume. Hence, it can only be stated that these activities took him into nearly all the coal producing states of the United States, to Canada, and to South America. In all phases of bituminous coal mining—reconnaissance, development, management and appraisal—he was, in Caesar's words, *facile princeps* (easily the first). This characteristic, with his early legal training and his well-known probity of character, made him a most impressive expert witness, in high esteem in the courts, and sought for in most of the important mining litigation originating in the Pittsburgh region.

Mr. Rayburn was held in high esteem by the members of his profession, by those who employed him, and by the people of the community in which he lived. His sturdy honesty and fine character are well exemplified in the words of Polonius in his advice to Laertes—*Hamlet*—Act I, Scene 3:

"This above all: to thine own self be true,
And it must follow, as the night the day,
Thou canst not then be false to any man."

This is indeed a brief of Mr. Rayburn's character, and accounts for his standing in the community, as well as with all who knew him.

He is survived by one daughter, and one son. A large circle of friends mourn his passing.

Mr. Rayburn was elected a Member of the American Society of Civil Engineers on April 17, 1917.

RALPH JOHN REED, M. Am. Soc. C. E.[1]

DIED JULY 27, 1939

Ralph John Reed, son of Arthur Lucius and Anna Virginia (Kelly) Reed, was born at Port Huron, Mich., on April 30, 1883, and went to Whittier, Calif., at an early age. He attended Pomona College, at Claremont, Calif., where he was graduated in 1905 with the degree of Bachelor of Letters. He also attended the University of Michigan, at Ann Arbor, Mich., where he was graduated in 1908 with the degree of Bachelor of Science in Civil Engineering.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LII, June (1904), p. 552.

[1] Memoir prepared by Harry W. Dennis, M. Am. Soc. C. E.

His subprofessional engineering work included surveying during the summers of 1903–1905 for hydroelectric projects in the mountains of California, instructing in surveying for the summer engineering camps while at the University of Michigan, and, after graduation, topographic surveys on the Huron River for the late Gardner S. Williams, M. Am. Soc. C. E. Also included was his early work with the Union Oil Company of California whose employ he entered in October, 1908.

This latter position, however, soon brought Mr. Reed into work of a professional nature which included the locating of long and important oil transportation lines, with their accessory pumping stations, and the design and construction of large concrete-lined oil storage reservoirs. From 1911 to 1914 he was in charge of the Engineering Division of the Union Oil Company at Los Angeles, Calif. In 1915 he was engineer of the transportation department in charge of rearranging and enlarging five main-line pumping stations, and was acting chief engineer during 1916 and 1917, becoming, in November, 1917, chief engineer. He continued as chief engineer, until he resigned in 1929, in charge of all engineering design and construction, particularly for the departments of sales, manufacturing, and transportation. The work included oil pipe lines, pumping stations, tanks and storage reservoirs, docks and marine terminals, warehouses and refineries, cracking plants, and natural gasoline plants. His work represented expenditures of more than $30,000,000.

In 1929 Mr. Reed became a consulting engineer in private practice. His notable engagements have included: Consultant for the repair and reconstruction of earthquake damage at a large department store following the Long Beach, Calif., earthquake; consultant for various oil companies on appraisals and new work; member of the Board of Economic Survey of the Port of Los Angeles; and consultant for the Los Angeles County Flood Control District on its rock-fill dams in the San Gabriel Canyon.

His scholastic ability was recognized by his election to the honorary societies of Sigma Xi upon his graduation from the University of Michigan, Phi Beta Kappa in 1914 by Pomona College, and Tau Beta Pi in 1928 by the California Institute of Technology, at Pasadena, Calif.

During the twenty-one years of his employment in the petroleum industry, Mr. Reed gained a wide experience in its technical branches. From 1925 he was active in the production division of the American Petroleum Institute (A. P. I.) with special reference to matters of standardization, fire protection, and corrosion study.

He served as national chairman of the A. P. I. Committee on the Standardization of Steel Tanks for Oil Storage from January, 1927, until April, 1930. He was the first national chairman of the committee, and it is largely due to his initiative, vision, and executive ability that the present A. P. I standards on A. P. I. steel tanks were developed to such a high degree of usefulness. He inaugurated the idea of preparing detailed shop drawings which are now (1939) in current use throughout the industry.

After his resignation as national chairman in 1930, he continued as chairman of the California District Subcommittee on Tanks until April, 1932. Upon completion of this period, he continued to serve as a member of the California District Committee until his death.

As national chairman of the A. P. I. Tank Committee, he was also a member of its Central Committee on Standardization, which is the general supervising agency of the Institute on all standardization matters. His high degree of intelligence and business sagacity were a distinct asset to that committee. He also served as a member of the A. P. I. California District Subcommittee on the Standardization of Tubular Goods from June, 1925, to February, 1939.

Mr. Reed was appointed to the State (California) Board of Registration for Civil Engineers on August 13, 1931, became a vice-president thereof on August 28, 1931, and was its president from January 30, 1933, to January 7, 1937. He was again its vice-president from January 7, 1937, until his death. He was also vice-president of the National Council of State Boards of Engineering Examiners from 1933–1934 and president from 1934–1935. He was a member of the Association of Professional Engineers of the Province of British Columbia, and of the American Society of Mechanical Engineers.

Mr. Reed gave freely of his time in connection with civic affairs. He was vitally interested in the development of Los Angeles Harbor and served on the Harbor Subcommittee of the Foreign Trade Committee of the Los Angeles Chamber of Commerce for many years. He was chairman of the subcommittee in 1938. He had a deep interest in matters of fire protection and safety, and was for a long time, until ill health prevented, a valued member of the Los Angeles Traffic Advisory Board. This organization was a volunteer group under the leadership of the Automobile Club of Southern California and was composed of representatives from the various divisions of the city government having jurisdiction over the control or direction of traffic, representatives from organizations in the transportation field, and others interested in, or affected by, the traffic problem. This Board serves as a forum in the interchange of ideas designed to effect improvements in traffic conditions.

Mr. Reed was married on June 9, 1909, to June E. Miller, who died in 1926. Two sons, John Miller Reed, born in 1914, and Robert Pearson Reed, born in 1921, survive. On September 23, 1929, Mr. Reed was married to Alberta P. Mann, who also survives him.

From 1923–1936 Mr. Reed was a director of the Los Angeles Young Men's Christian Association. At the time of his death he was a trustee of Pomona College; a director of the Whittier National Trust and Savings Bank; a director of the Beverly Hills Hotel Company; past master of Arlington Lodge No. 414, Free and Accepted Masons; and a member of Los Angeles bodies Ancient and Accepted Scottish Rite. He also was a member of the University Club (Los Angeles), the Engineer's Club (San Francisco), and the Rotary

Club (Los Angeles). In national politics he was a Republican, and in church affiliation he was a Congregationalist.

During his vacations he looked to mountaineering for recreation. He was a member of the Sierra Club whose purpose is "to explore, enjoy and render accessible the mountain regions of the Pacific Coast; to publish authentic information concerning them; to enlist the support and cooperation of the people and the Government in preserving the forests and other natural features of the Sierra Nevada." Pursuant to that objective, Mr. and Mrs. Reed accompanied the Sierra Club group for many of the excursions into the places where only the hardy and strong may hope to go.

He was President of the Los Angeles Section of the American Society of Civil Engineers in 1922 and was a Director of the Society, elected from District 11, from 1935–1937.

Mr. Reed was elected a Junior of the American Society of Civil Engineers on September 1, 1908; an Associate Member on October 1, 1913; and a Member on December 6, 1920.

EDSON MASON SCOFIELD, M. Am. Soc. C. E.[1]

Died December 28, 1939

Edson Mason Scofield was born in Hermon, St. Lawrence County, N. Y., on September 26, 1867. He was of true American lineage. His great-grandfather was personal aide to General George Washington and served in a continental regiment throughout the Revolutionary War.

His father, George Vincent Scofield, and his mother, Emily Jane (Mason) Scofield, were both descended from pioneer New England families which had lived first in Connecticut and then moved on to northern New York. His father was a hydraulic engineer and owner of a wood-working mill in Hermon where the son began to dream of his future vocation. His mother had been a school teacher, gifted both socially and intellectually, and she instilled into her son her own habits of precision and attention to detail.

Edson Mason Scofield, endowed with exceptional ability, passed with honor through the usual academic courses in the public schools of Hermon, and was graduated from high school in 1884. He then entered Union College, at Schenectady, N. Y., and in 1888 was graduated with the degree of Civil Engineer. In 1934, the degree of Doctor of Science was conferred upon him by Union College.

After teaching mathematics at Rockland College, Nyack, N. Y., for one year, he entered the field of engineering. From June, 1889, until March, 1903, Mr. Scofield was engaged successively as assistant to the late Edwin Thacher,[2] M. Am. Soc. C. E., nationally known bridge engineer of Louisville, Ky.; assistant engineer of the Youngstown Bridge Company, Youngstown, Ohio, then chief engineer and finally manager of the same company; and chief engineer of the National Bridge Company, Pittsburgh, Pa.

---

[1] Memoir prepared by Elisabeth Shaver, San Carlos, Calif.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 918.

In 1903, with his brother, the late Glenn M. Scofield,[3] M. Am. Soc. C. E., he organized the Scofield Engineering Company in Philadelphia, Pa., and served as president. The firm was successful from the start and rapidly won a nation-wide reputation for engineering ability and business integrity.

Mr. Scofield's inventive turn of mind was always ready to meet the opportunity when necessity arose. A notable instance was his invention of a form of slide-rule now in common use among engineers.

The vision, genius, and versatility in the early period of his career may be judged by the following achievements: The designing of a special power plant at Harwood Mines, Pa., capable of using a mixture of coal dust and dirt at the mouth of the mine, making the waste a principal source of revenue for the mine; a gas-operated high-pressure pumping station at Philadelphia, where a 300-lb pressure could be put on the fire mains in less than 40 sec; a power plant erected for the West Jersey and Seashore Railroad Company which furnished power to operate an electrified train running from Philadelphia to Atlantic City, N. J., within six months after work of construction was begun; a concrete dry dock in Mare Island Navy Yard, San Francisco, Calif., requiring the largest timber crib ever used up to that date, where work had to be done in 40 ft of soupy "Tule" mud.

Another important structure was a concrete dry dock at League Island Navy Yard, Philadelphia, the largest in that section at the time of construction, which was built under adverse conditions in a water-bearing gravel formation.

The steel frame for the U. S. Coaling Station at Manila, Philippine Islands, the coal handling equipment of the station at San Francisco Bay and at Guantánamo, Cuba, are among the achievements of the Scofield Engineering Company.

A storage and mixing plant for the Delaware, Lackawanna and Western Railroad at Delanson, N. Y., stored 300,000 tons of coal and enabled the owners to handle 1,000 tons per day out of cars into mixing piles and back into cars, and to ship a fine coal of uniform grade.

In 1918, the Scofield Engineering Company received government recognition and, under orders of the United States Shipping Board, began building reinforced concrete ships at San Diego, Calif., as the Pacific Marine and Construction Company. In 1920, the World War over, the office of the Pacific Marine and Construction Company was closed and the two brothers moved to Los Angeles, Calif.

The organization of the Scofield Engineering-Construction Company marked the passing of the old style contractor in favor of the technically trained expert. This concern was one of the first to feature the trained engineer in business. It was among the first to use the "cost-plus-a-fixed-fee" basis of construction whereby the owner is assured the most favorable cost of work consistent with sound construction and good investment. The company began specializing in large earthquake-proof buildings. Mr. Scofield had made an exhaustive study of earthquakes and earthquake protection. To his satisfaction none of the buildings erected according to methods based upon his research ever sustained more than minor cracks.

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1895.

In the period from 1920 to 1929, his company was responsible, either as engineers or as constructors, for the erection of approximately one hundred large buildings in and about Los Angeles. Some of the best known are the Biltmore Hotel and Theatre, the Pacific Mutual Building, Title Insurance Building, Barker Brothers, the Elks Club, the Good Samaritan Hospital, United Artists Theatre, all buildings of Sears-Roebuck Company, and the Pacific Finance Building.

Early in college days, Mr. Scofield became conscious of his personal responsibility in matters of public interest. That sense of responsibility was ever uppermost in his mind throughout the years crowded with diversified accomplishments. Always a valued public servant awake to the needs of the community in which he lived, Mr. Scofield was called upon by the Mayor of Los Angeles in 1929 to give his expert knowledge to the city of his adoption and he accepted membership on the Board of Water and Power Commission. No man could have been better qualified to appraise the future requirements of his locality and he turned the full force of his varied experience into the business of making the Power Bureau an asset to the public that owned it. In order to do his part, Mr. Scofield cut down his personal activities and gave more than three fourths of his time freely and gladly to this work.

He had watched Los Angeles become the metropolis of the West, the fifth city of the nation, in twenty years. He attributed the growth to the intelligent development of water and power facilities under ownership and control of the people. With characteristic insight, he looked ahead and saw an era of vast expansion in population and manufacturing industries and he was confident that the future growth of the metropolitan district and the complete development of the Pacific Southwest hinged upon the people's decision to take advantage of the Boulder Dam hydroelectric power.

He was among those who had fought with determination to induce the government to build Boulder Dam, and to no small degree must credit be given to his long experience in design, construction, and operation of utilities for the final consummation of this project. When at last the contract was signed for lease of power privileges between the U. S. Department of the Interior and the City of Los Angeles, he followed the immense construction job with satisfaction and gratification.

He responded to constant demand for speeches, for contributions to press and radio addresses. His words never failed to carry weight. His audiences caught his enthusiasm, recognized his rugged adherence to principle, his devotion to the cause he sponsored, and his freedom from selfish motive. He appealed to the people as owners of the Water and Power Department to complete the full program of the Colorado River Project by building a transmission system to bring an abundant supply of cheap power into their homes and factories.

In September, 1930, his connection with the Board of Water and Power was terminated. He had fought valiantly for the public enterprise against the opposition of its competitors and enemies, the private power companies, but was compelled finally to continue his efforts on behalf of the people in an unofficial capacity.

The Municipal Light and Power Defense League was organized by a group of prominent citizens who appreciated the immense benefit of a municipally owned Water and Power Department and who wished to see it protected and promoted to its maximum value. They sponsored a series of radio broadcasts and Mr. Scofield became one of their spokesmen. His weekly radio addresses stressed consideration of water and power as a business belonging to the citizens. To him the radio periods were in the nature of stockholders' meetings to discuss the best interests of business. Cheap light and power were the dividends.

It was highly fitting that he should be designated as a member of the general committee in charge of the Boulder Power Inaugural, on October 9, 1936, to celebrate the placing in service of the 266-mile transmission system—an event which marked the epochal step in the progress of the Southwest of which he dreamed and for which he had labored with diligence and faith.

The key to Mr. Scofield's character and work may perhaps be found in his own words, addressed to a club of young business men: "You are all young men at the acme of inquisitiveness. Don't be a conformist. Keep your faith. Faith should grow with knowledge and courage. There is need for the occasional man with faith and curiosity. There is need for inquiry."

His art of presenting technical facts in popular language is illustrated in his reference to the "romance hidden in the Owens Valley Aqueduct." "The momentum of each drop of water coming from 3800 feet elevation is captured over and over and transformed into electric power."

Mr. Scofield became a life student of unemployment, taxation, and all economic matters after his experiences in the panic of 1893. His research and the importance of his conclusions brought him into contact with the best informed opinion of the country. He believed that the cause of unemployment and the world-wide depression could be found in certain types of special privilege and private monopoly and it was his conviction that a gradual shift of the weight of taxes from the products of labor to the taxation of land values, exclusive of improvements, would discourage speculation in land, increase wages and interest, and so improve the condition of labor and capital. Wise beyond his generation, he knew that the world was not yet ready for this change and that the establishment of justice was not in the immediate future.

Mr. Scofield was married in Louisville, Ky., on February 20, 1894, to Lizziemac Rivers who died in 1930. They had two children, George Vincent and Alberta Bigelow (Mrs. Robert S. Bowen).

On January 21, 1932, Mr. Scofield was married to Ethel O'Shields of Los Angeles.

He was a member of the American Society for the Advancement of Science, the American Concrete Institute, Sigma Xi, California Taxpayers Association, Tax Reform Association, Los Angeles Chamber of Commerce, Orange County Coast Improvement Association, South Coast Improvement Association (was their first president, 1932–1933), X Club of Los Angeles, Los Angeles Country Club, Los Angeles Section of the American Society of Civil Engineers, Jonathan Club, Municipal League of Los Angeles, National Municipal League, Public Ownership League of America, Southern California Council on Earthquake Protection, and the Advisory Committee of California Development Association.

He was appointed by the 1939 Golden Gate International Exposition to be a member of the World's Fair Advisory Commission for the City of Los Angeles.

Mr. Scofield was a sponsor for the Henry George School of Social Science in Los Angeles. He was an able exponent of the Henry George philosophy which he considered a practical and unselfish way of living for the benefit of mankind.

Mr. Scofield managed to find time for recreation even in the midst of his many activities. He was an enthusiastic equestrian, and enjoyed golf, but the relaxation he valued most he found at his lodge in the mountains at Mammoth Lakes and at his seaside cottage on the south coast at Laguna Beach, Calif.

He spent many hours in a fully equipped, soundproof workshop adjoining his home, where he forgot the stress of business while his expert hands obeyed his creative direction.

Mr. Scofield was affectionately known as "E. M." to those who knew him best, and all those who came to him in friendly intercourse found the veil of outward reserve lifted and were at ease in the warmth of his human love and sympathetic understanding.

He was a true and trusted friend never too busy to give his full attention to every question presented; never too hurried to probe to the bottom of every perplexity by his own process of exact analysis. His counsel was sane and sure and he never permitted his tongue to say what his heart denied. In business as well as in his daily dealings with people everywhere he was known to be scrupulously honest.

Structures of stone and steel from Florida to Portland, Ore.—from New York to San Francisco—stand as silent witnesses to his mastery of engineering problems, but Mr. Scofield will be remembered and honored fully as much for the designs he conceived and the service he rendered to benefit the people of his time.

His boyhood ambition, revealed in reminiscent mood, "To be a good engineer and to do some good in the world," has been fulfilled beyond the measure of human standards.

Mr. Scofield was elected an Associate Member of the American Society of Civil Engineers on April 1, 1896, and a Member on May 2, 1905.

HAROLD BEMIS SHATTUCK, M. Am. Soc. C. E.[1]

DIED APRIL 25, 1939

Harold Bemis Shattuck, the son of Gilman C. and Estelle M. (Barnes) Shattuck, was born at Nashua, N. H., on November 17, 1873.

His early education was received in the public schools and high school of Nashua. In 1897 he was graduated from Dartmouth College at Hanover, N. H., with the degree of Bachelor of Science. He had taken the first year of the work of the Thayer School of Civil Engineering during his senior year and intended to complete the required subjects for the civil engineering degree. In accordance with this plan he secured employment as rodman with the Boston Electric Light Company in July, 1897, so as to meet the school's requirement for practical engineering work. However, he became interested in medicine, and in January, 1898, he entered Dartmouth Medical College. A serious illness compelled him to withdraw from college in July of that year and to give up the idea of becoming a physician. For some time he was unable to engage in work of any kind, but in November, 1900, he was employed as clerk by the Pines Hotel, Lakewood, N. J. He resigned from this position in April, 1901, to accept an appointment as assistant in civil engineering at The Pennsylvania State College, at State College, Pa.

Soon after this appointment, in addition to his teaching, he began taking subjects necessary to complete the work required for graduation in civil engineering and, as a result, was graduated from The Pennsylvania State College with the degree of Bachelor of Science in Civil Engineering in 1904. In 1915 he was granted the degree of Civil Engineer by the same institution.

He was promoted to the rank of instructor in July, 1903; assistant professor of civil engineering, in July, 1905; associate professor of railroad engineering, in July, 1908; and professor of railroad engineering, in July, 1924. During much of this time Professor Shattuck was in responsible charge of instruction in railway and highway engineering subjects. He retired from teaching because of physical disability on February 1, 1936, and was appointed professor emeritus of railroad engineering in recognition of his past services.

In addition to his college work, he had been engaged in private engineering practice since 1907—mainly in land surveying, municipal engineering, water supply, and sewerage. He was borough engineer of State College for twenty-seven and a half years, ending January, 1934, and he was borough engineer for several neighboring boroughs for short periods. He was elected county surveyor for Centre County, Pennsylvania, for three successive terms, serving from January, 1921, to January, 1933. He was also bridge engineer for the commissioners of Centre County in 1919, 1922, and 1923.

Professor Shattuck was a member of the American Railway Engineering Association, and he served as a member of Committee XVI, Economic Location. He was also a member of the American Association of University Professors, the Society for the Promotion of Engineering Education, the Pennsylvania Water Works Operators' Association, and the Centre County Engineers' Society.

---

[1] Memoir prepared by Elton D. Walker, M. Am. Soc. C. E.

While he was a student at Dartmouth, he became a member of Alpha Delta Phi and was elected to membership in Phi Beta Kappa in his senior year. At The Pennsylvania State College he became a member of Phi Kappa Phi and of Chi Epsilon. He was a Thirty-Second Degree Mason, a member of the Consistory, the Commandery, and the Shrine. He was active in the organization of the Blue Lodge at State College and served as Worshipful Master. He was a charter member of the Kiwanis Club and served on its board of directors, and was also a charter member of the University Club at State College. He was president of the board of trustees of the Presbyterian Church at State College for six years preceding his death and had been active in the affairs of the church for many years.

Professor Shattuck was married in 1909 to Elizabeth M. Stuart, of State College, who died December 25, 1934. They had no children. He is survived by two brothers, Arthur G. and Roger C., and by two sisters, Helen and Fanny C.

Professor Shattuck was a genial gentleman, a competent engineer, and a faithful teacher, liked and respected by his students and associates.

Professor Shattuck was elected a Member of the American Society of Civil Engineers on May 12, 1930.

BENJAMIN BRUCE SHAW, M. Am. Soc. C. E.[1]

DIED JUNE 2, 1939

Benjamin Bruce Shaw, the son of William Henry Shaw and Emma (Burrell) Shaw, was born at Canton, Ill., on February 21, 1886. His boyhood was spent in his native town where he received his early education, and where his father was the postmaster for twenty years.

Mr. Shaw was graduated in Civil Engineering at the University of Illinois, at Urbana, Ill., in 1911 with the degree of Bachelor of Science and in 1916 he secured the degree of Civil Engineer from the same institution. While still attending school his early technical training began in 1906 when, during summer vacations, he was employed as rodman and draftsman with the Illinois Central (Electric) Railroad Company, the city engineer of Canton, and with the Sanitary District of Chicago, Ill.

In July, 1911, Mr. Shaw began his first regular assignment on railroad construction with the St. Paul and Kansas City Short Line Railroad Company in Iowa and served in the capacity of estimator, rodman, and assistant engineer, respectively. In 1913, upon completion of the construction work, he was transferred to El Reno, Okla., as assistant engineer on the Chicago, Rock Island and Pacific Railway on construction and maintenance work. He was promoted to division engineer in January, 1915, with headquarters at Haileyville, Okla., and in 1916 was transferred to Little Rock, Ark., in the same capacity.

---

[1] Memoir prepared by Fred P. Funda, Assoc. M. Am. Soc. C. E.

During his service with the Chicago, Rock Island and Pacific Railway Company, he constructed extensive trackage, yard, and shop facilities at Little Rock and at El Dorado, Ark. With the discovery of oil at El Dorado in 1920, extensive railroad development in that territory was essential in order to handle the rush of men and materials to the new oil field, and Mr. Shaw planned and executed the construction work in record time. He accepted the position of chief engineer of the Cuba Railroad at Camagüey, Cuba, in December, 1922, and served in that capacity until July, 1925. During this assignment he constructed the Santa Cruz line from Camagüey to Santa Cruz del Sur, Camagüey, Cuba, and completed extensive port improvements at Antilla, Cuba, besides a general rehabilitation program of the Cuba Railroad to enable operation of larger locomotives.

Returning to the United States in July, 1925, Mr. Shaw was employed by several railway supply and contracting companies as sales and contracting engineer. In 1934 he was appointed manager of mills and mines of the Georgia Kaolin Company at Drybranch, Ga., which position he was holding at the time of his sudden death on June 2, 1939.

An engineer of ability, he combined with his technical knowledge and executive qualities a winning personality that would have carried him far in his chosen profession. His loyalty to his employers was outstanding, and his varied contacts among business and professional men gained him many strong friends who respected him for his affability, his conscientious work, and his uprightness of character. His intimate friends will not forget his jovial sense of humor and those rare qualities of mind and heart that so endeared him to all with whom he came in contact. In his professional and social life his courtesy and kindly consideration were never failing.

Mr. Shaw was married on August 4, 1913, to his boyhood friend, Elizabeth Henkle, at Canton. A kind husband, he loved his home and his devoted wife, who survives him. Although he had no children of his own, he believed in youth and giving the boys about him a worthy chance in life, and his kindness found expression in his deep interest in the lives of the individuals and families with whom he worked.

At the time of his death Mr. Shaw was a member of the Sigma Nu Fraternity, which he had served as commandant while at the University of Illinois; he was also a member of the American Railway Engineering Association, the Society of American Military Engineers, Ancient, Free and Accepted Masons, Rotary Club of Macon, Ga., and the Red Cross Board. He was councilman of the Boy Scouts of America.

Mr. Shaw was elected an Associate Member of the American Society of Civil Engineers on August 9, 1920, and a Member on May 8, 1922.

JULIAN CLEVELAND SMITH, M. Am. Soc. C. E.[1]

Died June 24, 1939

Born at Elmira, N. Y., on October 7, 1878, Julian C. Smith was the son of Howard M. and Mary Elizabeth (Joslyn) Smith. He received his education at the central high school, in Buffalo, N. Y., and was graduated from Cornell University at Ithaca, N. Y., with the degree of Mechanical Engineer in Electrical Engineering in 1900.

Gifted with unusual power of concentration and a keen memory, the new graduate was marked for success from the outset. Beginning his professional career, on graduation, as a draftsman with the late Wallace C. Johnson, M. Am. Soc. C. E., consulting engineer at Niagara Falls, N. Y., he remained there two years, when he became assistant to Mr. Johnson at Shawinigan Falls, Que., Canada, at a time when The Shawinigan Water and Power Company was beginning active operations.

This young man thus became associated with one of Canada's most important utilities, the expansion of which gave scope for his unusual talents. At the age of twenty-five he was superintendent of the company. He became vice-president when thirty-six, and three years later was vice-president and general manager. In 1933 he was elected to the presidency and for many years occupied the same position with affiliated and associated companies. He was also in charge, as consulting engineer, of a number of water power projects, including the Manitoba Power Company at Great Falls, Manitoba, and the Cedar Rapids plant on the St. Lawrence River, in addition to the company developments at Shawinigan Falls, La Gabelle, and elsewhere. He saw the company grow from small beginnings to one of the greatest of its kind in the world.

Mr. Smith was the author of several papers on water power development and transmission design and construction, principally in the *Proceedings* of The Engineering Institute of Canada. He was awarded the Sir Casimir Gzowski Medal of the Canadian Society of Civil Engineers (known as The Engineering Institute of Canada after 1918) as the leading contributor in Canada to the literature of the profession of civil engineering during the year 1913, for his paper, " The Design of High Voltage Transmission Lines."

His principal hobby was astronomy and he humored it by the erection of a large telescope on his property at Lake Memphremagog. When the problem was brought to his attention of producing a new and much more efficient type of depth sounding recorder, Mr. Smith undertook to work on the instrument. The type which had been used on naval and mercantile vessels for several years was particularly sensitive and not always reliable. The improvement of this instrument presented a problem, the solution of which required a high degree of technical skill. With the aid of one or two friends he succeeded, just before his death, in developing a machine greatly superior to that in use. It was given a thorough test by the group, who made a chart of Lake Memphremagog waters. The work was finished and the new instrument, marking a great advance on previous practice, was presented to the British Admiralty for use on naval vessels.

---

[1] Memoir prepared by Fraser S. Keith, Esq., Montreal, Que., Canada.

The eminent position held by him in the industrial, financial, scientific, and university life of Canada is evidenced from the following partial list of the positions he held: President of The Shawinigan Water and Power Company, Quebec Power Company, St. Maurice Power Corporation, United Securities Limited, and The Canada Light and Power Company; vice-president of The Royal Bank of Canada, Dominion Bridge Company, and Dominion Engineering Works; Director of Canadian General Electric Company, Consolidated Paper Corporation, Montreal Island Power Company, Montreal Trust Company, and Saguenay Electric Company; governor of the Montreal General Hospital, and McGill University; member of the National Research Council.

The Engineering Institute of Canada honored him with its presidency in 1928. For some time, prior to his death, he had been chairman of the Advisory Committee for Canada of the Institution of Civil Engineers of Great Britain. Two Canadian universities recognized his high standing by conferring on him the degree of Doctor of Laws—Queen's University in 1923 and McGill University in 1928.

He held membership in the following societies: American Institute of Electrical Engineers, Institution of Electrical Engineers of Great Britain, Institution of Civil Engineers of Great Britain, The Engineering Institute of Canada, and professional societies in Quebec and Manitoba. He was a member of important clubs in New York and Montreal.

Big business sought him for his wise counsel, financial organizations for his keen discernment, research and educational institutions for his breadth of vision, and many individuals for his sympathetic advice and generous assistance. Few men have left a greater record of achievement and none has been more sincerely mourned.

Rarely are found in one person such admirable qualities as were possessed by Mr. Smith. His unusual vision and profound technical knowledge were the mainsprings of a great industrial empire. His clarity of judgment enriched many of Canada's leading organizations. Great as were his qualities of mind, his nobility of character and open-hearted generosity of spirit were the attributes that, like a magnet, drew men to him in affectionate regard.

Surviving are Mrs. Smith (Bertha Louise Alexander), two sons, Julian C. and Joslyn A. (both of whom are engineering graduates), two daughters, Mrs. R. Harvey-Jellie and Mrs. J. Desbaillets.

Mr. Smith was elected a Member of the American Society of Civil Engineers on October 2, 1922.

WILLIAM PLINY SNOW, M. Am. Soc. C. E.[1]

Died October 12, 1938

William Pliny Snow was born in Charlton, Mass., on May 19, 1855, the son of Franklin Thurston and Sophia (Kidder) Snow. He was descended from Colonial forbears, some of whom fought in the Revolutionary War.

In 1862 the family moved to the town of Roxbury, Vt. William fitted himself for college at Barre Academy, and was graduated from Dartmouth College at Hanover, N. H., with the degree of Bachelor of Science, in 1881.

He began active engineering work in 1881 as a topographer for the Rocky Mountain Division of the Northern Pacific Railway Company in Montana, which was still largely an uncharted wilderness. When the Northern Pacific Railway was opened, in 1884, Mr. Snow joined the staff of the surveyor general's office at Helena, Mont. There he gathered the material for his monumental map of Montana, the first complete map of the state which had ever been made.

After a short stay in Florida as assistant engineer in charge of construction for the Blue Spring, Orange City and Atlantic Railroad Company, he returned to Montana as assistant engineer in charge of construction for the Great Northern Railway Company. During that period he constructed more than 30 miles of roadbed. In his later years Mr. Snow often referred to his interesting pioneer experiences in Montana as among the most enjoyable of his career.

He left Montana in 1888 and returned to New England and began the type of work which was to engage most of his interest and attention for the rest of his life—that is, mill construction, and hydraulic developments for factories. A list of the important works which Mr. Snow executed with great distinction would be a long one.

His first engagement after returning from Montana was with the Parsons Paper Company at Holyoke, Mass., where he designed and supervised the construction of the raceway, wheel pits, and headgates. In 1889 he built the earthen dam for the water works at Hinsdale, Mass., and repaired the dam for the Sadauga Reservoir at Whitingham, Vt.

In 1890 Mr. Snow attracted the attention of Stephen Greene, then the head of the engineering firm of Lockwood-Greene and Company. Mr. Snow joined the Lockwood-Greene organization at that time and remained with them almost continually until his retirement in 1935 at the age of 80.

Mr. Snow became the most highly trusted construction engineer in this company. He was assigned usually to work that required ingenuity in design, care in construction, and ability to get along well with owners and contractors. Mr. Snow, with his wide experience, careful training, good nature, and unimpeachable integrity, filled the requirements in a very unique way.

---

[1] Memoir prepared by Albert L. Scott, M. Am. Soc. C. E.

The most important projects that Mr. Snow supervised during the 45 years of service with Lockwood-Greene and Company include the following:

1890 to 1891	—The rebuilding of the Dunnell Manufacturing Company plant at Pawtucket, R. I.;
1892	—Design of dams for Pacolet Manufacturing Company, Pacolet, S. C.;
1893 to 1894	—Pelzer Manufacturing Company, Pelzer, S. C., and Tucapau Mills, Tucapau, S. C.;
1896	—Rearrangement of plant of Androscoggin Mills at Lewiston, Me., and building a new plant for the Liondale Bleachery, Rockaway, N. J.;
1898	—Design of a 500-ft canal for Bodwell Water Power Company, Oldtown, Me.;
1900	—Design of stone dam for Palmer Mills, Three Rivers, Mass.; rebuilding and remodeling Lonsdale Bleachery at Lonsdale, R. I.—this operation was executed without curtailing output.

In 1902 Mr. Snow became a general consulting engineer for Lockwood-Greene, assisting in the design and supervision of the dams of the Greenville Carolina Power Company, at Greenville, S. C.; the Rockingham Power Company, at Rockingham, N. C.; and the Central Georgia Power Company, at Flovilla, Ga. He became more and more in demand as an expert in examining, correcting, and modernizing reports made by other engineers. Clients wanted Mr. Snow's opinion on problems considered to be of an unusual or intricate nature, particularly those having to do with water powers, wheel installations, design of canals, forebays, wheel pits, and tailraces. In later years he became the most experienced hydraulic engineer in the Lockwood-Greene organization and found hydraulic work most fascinating. He was the first choice of his superiors and often of the owners for designing and supervising unusual construction and remodeling work.

As previously mentioned in this brief summary, Mr. Snow was particularly felicitous in his dealings with clients and contractors on difficult remodeling, rearranging, and repair work, where output had to be maintained, and changes made, frequently without finished plans or opportunity for bidding. Mr. Snow's character and reputation for fairness generally made both owner and contractor agree to any decision he might make.

Mr. Snow was slight in stature, quick in motion, lean and active to the last. He had a gentle winning smile, rare tact, unfailing urbanity, and a faculty for seeing all sides of a question. He was a sound engineer, an unfailing friend, and unusually able in working with other people, with a long and honorable career in his chosen profession.

Mr. Snow was married on May 14, 1884, to Emma J. Paul. He is survived by his widow, and a daughter, Florence (Mrs. F. I. Miller).

Mr. Snow was elected a Member of the American Society of Civil Engineers on February 5, 1902.

WILLIAM WARBURTON KNOX SPARROW, M. Am. Soc. C. E.[1]

Died November 7, 1939

William Warburton Knox Sparrow was born at Moneymore, County Tyrone, Ireland, on December 30, 1879, the son of the Rev. William and Cecilia Jane (Knox) Sparrow. His father was a clergyman of the Episcopal Church. Mr. Sparrow was educated in England and entered railway service in Ireland in February, 1896, in the engineering department of the Belfast and Northern Counties Railway Company.

In December, 1898, with a desire for adventure, as he once described it, he left Ireland for South Africa, obtaining employment with the Cape Government Railways in February, 1899. From that time until November, 1908, he was engaged continuously on railroad location, and construction and maintenance work. For two years of this period he was with the Charter Company of Rhodesia (Cecil Rhodes' company) on location of railroads and highways.

In 1908, while he was in South Africa, Mr. Sparrow passed the necessary examination and was elected an associate member of The Institution of Civil Engineers, London, England.

Although recognizing the advantages of government service and the feeling of security that it afforded, Mr. Sparrow realized that the opportunities for self-development were limited due, for one thing, to the fact that all positions were under civil service, requiring strict adherence to seniority rules for advancement. After much consideration, he decided to try his fortune in the United States.

He and his wife, the former Mary Batchelor, left Capetown, Union of South Africa, on their wedding day, late in November, 1908, arriving in the United States early in 1909. Neither of them had any acquaintance in the United States, but Mr. Sparrow had, through reading some of his books, heard of the late J. A. L. Waddell, Hon. M. Am. Soc. C. E., consulting engineer of Kansas City, Mo. He decided to go there and present his case, hoping that the fact that he had come from South Africa to see him would make a sufficient impression to gain him work in Mr. Waddell's office. He was given a place in the drafting room of Waddell and Harrington at a salary of $50 a month.

Thus, after having spent almost ten years in South Africa, he started anew in a strange country, later to become the country of his adoption; sustained by a keen desire for self-development and an opportunity to work in the knowledge that the reward would be measured by the worth of one's efforts.

Mr. Sparrow remained with Waddell and Harrington until July, 1912. During his service with that firm he worked as a detailer, checker, and designer on concrete and steel bridges, occupying the position of assistant designing engineer when he left. These three years were indeed trying ones, but his was the determination to solve the problem at hand and overcome obstacles, a characteristic of his entire life. In those years, as in all of the years that followed, he was fortunate in having the encouragement and sympathetic understanding of his ever devoted and loyal wife.

---

[1] Memoir prepared by John J. Roche, Esq., Chicago, Ill.

From July, 1912, to September, 1913, Mr. Sparrow was associated with the late Hans von Unwerth, M. Am. Soc. C. E., consulting engineer of Kansas City, in architectural engineering.

With the creation of the Missouri Public Utilities Commission, Mr. Sparrow's interest turned to the possibilities of service there, and in September, 1913, he took a position as assistant engineer, later becoming assistant chief engineer of that commission. After coming from South Africa to get away from the restrictions of government service, it seemed inconsistent to take a position with another government body, but it gave him what he wanted—an opportunity to get acquainted with people, especially railroad people. His work comprised inspection and valuation of railroad property in the State of Missouri. Through his service with the commission he secured his first railroad position in the United States—that of valuation engineer of the Chicago, Burlington and Quincy Railroad Company, in April, 1916. Here he developed an organization to carry on the valuation work required by the Valuation Act.

In September, 1918, he became corporate chief engineer of the Chicago, Milwaukee and St. Paul Railway Company and continued in that capacity until the termination of federal control of railroads.

The succeeding years of his life were spent in the service of the Milwaukee Road. In June, 1920, he was appointed assistant to the President, in charge of federal valuation and settlement with the United States Railroad Administration for claims arising out of federal control. In November, 1920, he was placed in charge of the Accounting Department which, while indeed a new field to him, was a recognition of his capacity for organization and executive ability. The Real Estate Department, which he was instrumental in establishing in December, 1921, was added to his jurisdiction.

In 1923 Mr. Sparrow was elected vice-president of the company and was assigned to handle financial matters in addition to his accounting, real estate, and valuation work. During the period of receivership of the Chicago, Milwaukee and St. Paul Railway, from 1925 to 1928, he was chief financial and accounting officer for the receivers.

In January, 1928, Mr. Sparrow was elected vice-president and a director of the newly organized Chicago, Milwaukee, St. Paul and Pacific Railroad Company, successor of the Chicago, Milwaukee and St. Paul Railway Company. Upon the appointment of trustees in bankruptcy, on January 1, 1936, Mr. Sparrow was appointed officer in charge of finance, accounting, and real estate, which position he occupied at the time of his death.

Mr. Sparrow was a man of strong convictions and outstanding ability. Trained in the engineering profession, he advanced to positions of responsibility in the broader field of railway management. He embraced responsibility, and to each new problem applied a keen power of analysis, persistence of effort, and intensity of purpose. While exacting in his requirements of others, he was no less exacting in the standards he set for himself, for he strove for perfection in whatever he attempted, to the accomplishment of which he devoted his energies unsparingly. Fair in his judgment and conscientious in his dealings, he was ever thoughtful and considerate of those on whom misfortune had fallen, and was always ready to help alleviate their distress.

For recreation, Mr. Sparrow was fond of golf and shooting and had a keen appreciation of literature, art, and music. He was devoted to home and family.

Mr. Sparrow was a member of the Railway Accounting Officers Association, Glen View Club, Western Railway Club, Electric Club of Chicago, and held a life membership in the Art Institute of Chicago. He was a director of the Mercantile National Bank of Chicago.

In addition to his widow, he is survived by two daughters, Jessie Cecilia Knox Sparrow (Mrs. George L. Green) and Eileen Knox Sparrow (Mrs. Elmer B. Rich, III); one son, Joseph Knox Sparrow; and two brothers.

Mr. Sparrow was elected an Associate Member of the American Society of Civil Engineers on December 6, 1905, and a Member on November 26, 1918. He passed away shortly before he was to have received a certificate of life membership in the Society.

EMBERT HIRAM SPRAGUE, M. Am. Soc. C. E.[1]

Died March 9, 1940

Embert Hiram Sprague, for many years Professor of Civil Engineering, then later Professor of Sanitary Engineering, at the University of Maine, Orono, Me., died very suddenly on March 9, 1940.

Mr. Sprague was born in Haverhill, Mass., on December 20, 1875, the son of Henry S. and Abbie (Nichols) Sprague. He received his early education in the schools of Haverhill, and in 1900 was graduated from Dartmouth College, at Hanover, N. H., with the degree of Bachelor of Science in Civil Engineering. He was a member of Theta Delta Chi, a social fraternity, and Casque and Gauntlet, a senior society.

Upon graduation from Dartmouth, he worked for three years as a draftsman—first for the New England Telephone and Telegraph Company, then the Pencoyd Plant of the American Bridge Company, and finally the Riter Conley Company of Pittsburgh, Pa. In 1903, Mr. Sprague went to South Africa to take the position of bridge engineer for the Central South African Railways. After about a year, he was engaged by the Blaisdell Company of Los Angeles, Calif., to supervise the erection of special sand excavators for mining reduction plants at Johannesburg, Union of South Africa. In March, 1905, he accepted a position with the H. Eckstein Company, mining engineers in Johannesburg, designing layouts for Blaisdell sand-treatment plants. Later he became sampler and surveyor for the Nourse Mine. Following 1908, Mr. Sprague spent much time with the Consolidated Gold Mines of South Africa, where he was in charge of underground workings. It was here that he originated and made a new type of assay plan.

---

[1] Memoir prepared by Weston S. Evans, M. Am. Soc. C. E.

Returning to the United States in 1909, Mr. Sprague accepted the position of chief engineer with the Mulcahy and Gibson Company, later going with Post and McCord of New York, N. Y., on steel building construction. During the latter part of 1914, Mr. Sprague worked as resident engineer for the Maine State Highway Department on bridge erection.

In February, 1915, he was appointed to the position of Associate Professor in the Department of Civil Engineering at the University of Maine. In this capacity, he soon became acting head of the Department of Civil Engineering, and was appointed head of the Department in 1926. He became Professor of Sanitary Engineering in 1934, and served in this capacity until his death.

During Professor Sprague's appointment at the University of Maine, he received many honors, among them election to the honorary societies of Tau Beta Pi and Phi Kappa Phi. He was a member of the Masonic order and several local and national professional societies.

On August 28, 1919, Professor Sprague was married to Addie Stockwell of Bangor, Me., who survives him.

In his chosen field, Professor Sprague had the respect and confidence of his colleagues. He found great pleasure in helping his students, to whom he endeared himself by his friendliness and kindly interest. He was always ready to do anything in his power to help both his students and his associates on the faculty.

Professor Sprague was elected a Member of the American Society of Civil Engineers on March 5, 1928.

WILLIAM SHACKELFORD SULLIVAN, M. Am. Soc. C. E.[1]

DIED DECEMBER 20, 1938

William Shackelford Sullivan, son of William K. Sullivan and Amelia (Shackelford) Sullivan, was born in Chicago, Ill., on May 19, 1885.

The son of a one-time owner and editor of the *Chicago Evening Journal*, and a well-known writer, he was educated in the public schools of Chicago and the Lewis Institute of Chicago. He entered the University of Michigan, at Ann Arbor, Mich., in 1901, joining the Phi Kappa Psi fraternity (Michigan Alpha). His college career was interrupted by ten years of working, but he returned in 1913 and was graduated in 1914 with the degree of Bachelor of Civil Engineering.

Mr. Sullivan served as draftsman with the Indiana Harbor Railroad Company in Chicago from 1905 to 1907, and with the Northern Pacific Railway Company in Montana from 1907 to 1910. From 1910 to 1911 he was resident engineer for the Kettle Valley Railroad Company, and held the same position with the Canadian Northern Pacific Railroad Company from 1912 to 1913. He was associated with Dean Mortimer E. Cooley, Hon. M. Am. Soc. C. E., of Ann Arbor, as chief of party on railroad valuation from 1914 to 1916.

---

[1] Memoir prepared by J. W. Follin, Assoc. M. Am. Soc. C. E.

After a year of private practice in structural engineering at Oakland, Calif., he became structural engineer for the Interstate Commerce Commission, Valuation Department, at San Francisco, Calif. Thereafter he was structural engineer successively for the Nevada State Highway Commission, at Carson City, Nev.; the Liberty Shipyard, at Alameda, Calif.; with Alfred P. Fisher, Assoc. M. Am. Soc. C. E., in San Francisco; and finally with the Pacific Coast Steel Company, in San Francisco.

From May, 1920, to July, 1922, Mr. Sullivan was mechanical inspector for the Pullman Company, at Richmond, Calif. After another year of private practice he became structural designer in the Bridge Engineers Office of the Southern Pacific Railroad Company, in San Francisco, leaving in March, 1924, to become assistant engineer, Department of City Transit, in Philadelphia, Pa., in charge of design and plans in connection with the Broad Street subway. He served this department until 1926. For the next twelve years, Mr. Sullivan resided in Washington, D. C., except for brief periods. He was structural engineer for the Arlington Memorial Bridge Commission from 1926 to 1933, at which time he became associated with the Public Works Department of the Navy, at Pensacola, Fla., as associate engineer (structural), and later with the War Department (Quartermaster Corps), as associate structural engineer. From 1936 to 1937 he was in the U. S. Engineers Office of the War Department on flood control at Bolling Field in Texas, and was later transferred to the flood control project at Cumberland, Md. At the time of his death he was associated with the W. F. Jackson Company, Inc.

An unusually good chess player, he was a member of the Board of Directors of the Capitol City Chess Club. He also won a number of cups in bridge tournaments.

Mr. Sullivan had been a member of the Philadelphia Engineers Club and the University Club of Washington, D. C. He never married and is survived by his sister, Helen (Mrs. James G. Cumming).

He was registered with the State Registration Board for Professional Engineers in Pennsylvania.

Mr. Sullivan was elected a Member of the American Society of Civil Engineers on December 14, 1925.

FREDERICK HORACE TIBBETTS, M. Am. Soc. C. E.[1]

DIED AUGUST 2, 1938

Fred H. Tibbetts will probably be best remembered for his extensive flood-control, reclamation, and irrigation work in the Sacramento Valley and his highly successful water-conservation project in the Santa Clara Valley. However, his field of activity during a period of some thirty years of engineering practice extended well beyond the limits of the State of California, and embraced many of the varied branches of the profession. Few engineers in the history of California have contributed so extensively to the development of its agricultural lands and the control and conservation of its waters.

---

[1] Memoir prepared by Ralph G. Wadsworth, M. Am. Soc. C. E.

Frederick Horace Tibbetts, the elder of the two sons of Horace Albert and Manda (Arnold) Tibbetts, was born at Oshkosh, Wis., on April 28, 1882. The family moved west when he was ten years old and settled in Santa Clara County, California. He attended the College of the Pacific, then at San José, Calif., and received his degree of Bachelor of Science in 1903. He continued his studies during the following three and one half years at the University of California, at Berkeley, Calif., receiving a degree of Bachelor of Science in Civil Engineering in 1904, and a degree of Master of Science in 1907. In the meantime, he had received a degree of Master of Science from the College of the Pacific in 1905.

While doing his graduate work at the University of California, he also served on the faculty as an assistant in civil engineering in the fall of 1904 and again in the academic year 1906–1907. In 1905 and the spring of 1906, he was an instructor in mechanics at the California School of Mechanical Arts in San Francisco. In August, 1907, he was appointed instructor in civil engineering at the University of California, and in July, 1909, became an associate professor, which position he held until 1911. He was elected to membership in three scholarship fraternities: Sigma Xi, Tau Beta Pi, and Sigma Iota Phi.

Mr. Tibbetts' active professional work commenced immediately after he received his first college degree and continued concurrently with his advanced studies and his teaching. Early engagements included surveys in Santa Clara and Alameda counties (1903), irrigation and drainage investigations (1904), and well measurements and surveys (1905). From 1906 to 1909 he was in charge of artesian investigations in Livermore Valley and the Pleasanton Reclamation Project.

In 1909, Mr. Tibbetts entered into a partnership with Perry A. Haviland, county surveyor of Alameda County, which lasted for nine years. The firm operated under the name of Haviland and Tibbetts, except in 1913 and 1914, during which period the name was changed to Haviland, Dozier and Tibbetts. The firm designed and supervised the construction of a wide variety of projects throughout central and northern California. During this period, Mr. Tibbetts was in charge of reports, estimates, designs, and supervision of construction of sewage systems and sewage disposal works for numerous cities and towns. He also handled designs, estimates, and reports on extensive harbor improvements at Richmond and South San Francisco, a highway system in Santa Barbara County, a filtered water supply for the City of Richmond, and all of the larger reclamation projects in Yolo Basin lying west of the Sacramento River above and below the City of Sacramento. The latter projects, particularly Reclamation Districts Nos. 900 and 999, which Mr. Tibbetts designed and in part supervised, included massive levees, drainage canals, and pumping plants. He also supervised extensive improvements of a similar nature in Reclamation District No. 70 in the upper part of Sutter Basin.

In November, 1912, Mr. Tibbetts submitted (on behalf of the firm of Haviland and Tibbetts from a branch office which had been opened in San Franciso) a report on the Knights Landing Ridge Cut, which had a major influence on the reclamation of the upper part of the Sacramento Valley. The cut, which forms an artificial outlet for flood waters in Colusa Basin, was sufficiently completed to be of immense benefit during the great 1915 flood. The project required more than 3,000,000 cu yd of excavation and the construction of highway and railroad bridges and various other structures. This work was followed immediately by the construction of major flood-protection levees and drainage systems in Colusa Basin, including particularly the construction of 50 miles of river levee between Knights Landing and Colusa.

In 1918, the firm of Haviland and Tibbetts was dissolved because of Mr. Haviland's ill health, and Mr. Tibbetts took over the San Francisco office under his own name. He continued as chief engineer of the Colusa Basin projects, previously undertaken for Reclamation District No. 108, the Sacramento River West Side Levee District, and the Knights Landing Ridge Drainage District. These three districts, which overlapped in part, provided complete flood protection for more than 100,000 acres of land which had been subject to frequent flooding by both river overflow and foothill drainage. In addition, Reclamation District No. 108 provided a complete drainage system and five separate irrigation systems for its 58,000 acres.

Mr. Tibbetts also became chief engineer of four additional large reclamation districts; two important water conservation districts; seven irrigation districts, including the two largest ones in the Sacramento Valley; two large land development companies; and a hydroelectric power company at Anchorage, Alaska. For all of these projects, and numerous other smaller ones, he prepared reports, estimates, and designs, and actively supervised construction, performed usually by contract, but in a few instances by force account. Included among the projects were several of the largest gravity intakes and pumping plants on the Sacramento River; the first wood screw pumps in California; irrigation and drainage canals with capacities to 1,500 cu ft per sec, constructed with floating dredges; levees built by the world's largest clamshell dredges, and others built with suction dredges; two steam-electric generating plants; the first modern rock-fill dam in California, 160 ft high; five concrete arch dams; seven earth-fill dams; and innumerable incidental structures such as bridges, headgates, siphons, flumes, roads, etc.

Among the various irrigation projects, two were particularly outstanding for their magnitude, their comprehensive planning, and their widespread public benefit. The Nevada Irrigation District in Nevada County, California, developed a water supply by diversion and storage at high elevation in the mountains and made a long-term contract for sale of the energy content of the falling water on such a basis as to amortize the full cost of the mountain works, thereby giving the agricultural lands at lower elevation what amounted to a free water supply. The mountain works included a 4-mile diversion tunnel, 85,000 acre-ft of storage, and an 11-mile conduit in rough terrain which required numerous flumes and tunnels. The irrigation distribution system included two large concrete diversion dams as well as many miles of canals and numerous structures. Total construction costs amounted to about $7,000,000.

The second outstanding irrigation project was one undertaken for the Santa Clara Valley Water Conservation District for the purpose of replenishing the underground water supply. The district, largely planted to orchards, was irrigated almost entirely by pumping from wells and, to 1934, the ground-water table had been dropping continuously at the rate of about 5 ft per yr until some of the pumping lifts were in excess of 200 ft. This condition was remedied by the construction of six detention reservoirs in the foothills and various regulating and distributing works in stream beds designed to retard runoff and induce percolation into the underground storage basin. A definite rise of the ground-water level has been experienced since completion of this work. The total cost of this project was about $3,000,000.

In addition to his engagements as engineer in complete charge of construction projects, Mr. Tibbetts was also employed as a consultant by many public and private agencies, including two irrigation districts in Nevada, a water conservation district in Arizona, four California cities, several land development companies and contracting firms, and numerous individuals and organizations. His services in connection with these engagements covered a wide variety of activities, including design of dams, investigation of water supplies, both surface and underground, subdivisions, irrigation systems, sewage disposal plans, harbor studies, water-works appraisals, and expert court testimony in water rights and other litigation. He made an extensive appraisal of the water rights and physical works of Miller and Lux, Inc., and the San Joaquin and Kings River Canal Company, and appraised the lands flooded by the Pardee Dam of the East Bay Municipal Utility District. He designed the Hogan flood-control dam on the Calaveras River for the City of Stockton, Calif. He directed final construction work for the contractors on the Wawona tunnel in Yosemite Valley and advised other contractors on tunnel problems. He was employed by the State Department of Public Works as a consultant on the Sacramento Valley unit of the Statewide Water Plan.

In spite of his very active professional practice, Mr. Tibbetts found time for many civic and fraternal duties. He was chairman of the Irrigation Section of the Commonwealth Club of California for three years (1925–1927), and was an occasional speaker for the Regional Planning Association of San Francisco (1925–1926). He was an active Mason, being a Past Commander of Oakland Commandery, Knights Templar, and holding office at the time of his death in Durant Lodge, in Berkeley, and Islam Temple of the Shrine, in San Francisco. He belonged to the University Club, Engineers' Club, and Olympic Club of San Francisco, and at times was a member of the Athens Club of Oakland, the Sutter Club of Sacramento, and the Arizona Club of Phoenix, Ariz. He was also a member of the American Institute of Electrical Engineers and the American Geophysical Union.

Mr. Tibbetts was married, first, to Edith Jean MacKerricher (in 1905), and second to Flora McDonald, who died only a few weeks prior to his own death. He is survived by his son by his first marriage, D. Reginald Tibbetts, and by his brother, Sydney A. Tibbetts.

During his active career, Mr. Tibbetts established a reputation as a keen thinker and a fluent speaker. He was unusually adept in presenting engineering problems to lay clients through both the written and spoken word. He had marvelous capacity for mastering and remembering intricate details of engineering theory and practice. He was a delightful companion and had a host of friends and acquaintances. He read extensively on a wide range of subjects and was particularly well informed on the strategy of the major military engagements of history. His hobbies were farming, photography, and aeronautics.

Mr. Tibbetts took a keen interest in Society affairs and contributed discussions on many subjects. He served on several important committees of the San Francisco Section and was a member of the Executive Committee of the Irrigation Division of the Society in 1927, 1928, and 1929, serving as chairman for the last two years.

Mr. Tibbetts was elected a Junior of the American Society of Civil Engineers on May 1, 1906; an Associate Member on April 6, 1909; and a Member on September 11, 1917.

ROSS KERR TIFFANY, M. Am. Soc. C. E.[1]

DIED JUNE 1, 1939

Ross K. Tiffany was born on June 11, 1879, at Union, Iowa, a son of Walter G. and Harriet (Kerr) Tiffany. After attending the grade and high schools at Union, he entered Cornell College at Mount Vernon, Iowa, from which he was graduated with a degree of Bachelor of Science in Civil Engineering and later was awarded the degree of Civil Engineer. While attending college, in 1899 and 1900, he obtained his first engineering experience in railroad location and construction—first in the Snake River Canyon with the Northwest Railway Company, and later in Missouri and Illinois with the St. Louis and New Orleans Railway Company.

Mr. Tiffany became a resident of the State of Washington in 1901 when he was employed as an engineer by the Washington Irrigation Company on Sunnyside Project, the largest single irrigation undertaking in the state at that time. The company was supplying water to about 43,000 acres of land and was actively engaged in planning storage at the headwaters of the Yakima River to water additional land in the lower Yakima Valley. He became chief engineer of the Washington Irrigation Company in 1903 and resident manager in 1906. From that year until 1910 he supervised all land-development operations undertaken by the Company. In 1905 and 1906 he took an active part in procuring limiting agreements with respect to the use of water among water users in the Yakima Valley, a step that was necessary before the government could be justified in acquiring the Sunnyside Project and undertaking extensive development in other parts of the valley.

---

[1] Memoir prepared by a committee composed of R. C. Knapp and F. H. Rhodes, Jr., Associate Members, Am. Soc. C. E., and G. L. Parker, M. Am. Soc. C. E.

Mr. Tiffany was employed in 1910 by the U. S. Reclamation Service as superintendent of the Sunnyside unit of the Yakima Project. In 1914 he was advanced to manager of the Yakima Project, in charge of operating and maintaining its several separate irrigation units and of its extensive storage developments. While project manager he helped to place collections on a business basis by organizing irrigation districts and was instrumental in discouraging land speculation.

Mr. Tiffany voluntarily left federal service in 1920 to engage in consulting engineering practice at Spokane, Wash. While there he was project engineer and project manager of the Spokane Valley Canal Company. He supervised the refinancing of Post Falls, Hayden Lake, and Dalton irrigation projects and the reconstruction of Lewiston Orchards Canal system. An important engagement during this period was negotiation leading to a final settlement of questions at issue between landowners and the Twin Falls North-Side Canal Company in Idaho.

In April, 1925, Mr. Tiffany was appointed supervisor of hydraulics in the Washington State Department of Conservation and Development. In that capacity he represented the State of Washington on the Columbia River Allocation Board, reorganized the Division of Hydraulics, increased state revenue therefrom fivefold, and handled a large increase of activities without an increase in personnel. He resigned in November, 1929, to undertake the private practice of engineering again with his office at Olympia, Wash.

Mr. Tiffany's second venture into the field of consulting engineering covered a period of more than four years during which he filled a wide range of engagements involving irrigation, drainage, diking, water supply, and water power. He was appointed by President Herbert Hoover, Hon. M. Am. Soc. C. E., to the Commission on Conservation and Administration of the Public Domain. The Commission finished its investigation in the fall of 1930 and rendered a published report in January, 1931. During the worst part of the depression, from March, 1933, to February, 1934, he served as works manager of the Washington Emergency Relief Administration, supervising an unemployment relief program financed by an emergency state bond issue of $10,000,000.

In March, 1934, Mr. Tiffany was appointed executive officer of the then newly created Washington State Planning Council, an office which he held until his death. Perhaps the most constructive accomplishment of his career was with that agency. He was eminently qualified for the office through intimate knowledge of the state and of its varied and abundant natural resources. He visualized extraordinary opportunities for the future use and control of those resources and recognized how vital planning activities are, and will become, in guiding proper development. His enthusiasm, energy, foresight, and tact proved to be invaluable assets to the Planning Council. How well they were appreciated may be judged from the following quotation included in a resolution passed shortly after his death:

> "Mr. Tiffany possessed in a high degree the rugged physique, the capacious mind, the high character, the broad outlook and the exploratory spirit that distinguished those who pioneered in the development of the West. Added to these striking qualities was the imaginative sweep of vision, and the constructive understanding of the needs and opportunities of this Pacific Northwest that made of him a great leader and builder."

Some of Mr. Tiffany's outstanding traits of character, which largely account for his steady professional rise, were his unusual geniality; his capacity to make and hold friends; his loyalty to friends; his effectiveness in promoting team-work and good-will among colleagues, employees, clients, and others; his liberal sense of humor; his fairness and integrity; his technical and administrative competency; and his energetic devotion to the immediate task at hand. All of these were sustained and provided with driving force by exceptional physical vigor and radiant health. His wholesome well-being was responsible to some extent for his untimely death. He was unwilling to remain quiet and inactive long enough to recover properly from a serious automobile accident.

Mr. Tiffany was married to Ella Eicher, of Ainsworth, Nebr., on July 3, 1903. They became the parents of a son, Ross Kerr, Jr., a civil engineer with the Bureau of Reclamation at Grand Coulee Dam, and a daughter, June (Mrs. Robert C. Thurston).

Wherever located, Mr. Tiffany took an active part in civic enterprises. He served as mayor of Sunnyside in 1908, as trustee and president of the Yakima Chamber of Commerce in 1918 and 1919, and as trustee of the Spokane Chamber of Commerce. As a member of the Rotary Clubs of Spokane and Olympia, he helped sponsor many beneficial local undertakings. He was the prime mover in organizing the Washington Irrigation Institute in 1914, served as its president in 1921 and 1922, and thereafter was made an honorary life member. He was a past-president of the Association of Engineers of Spokane. His tactful influence was an important factor in formulating a water code for the State of Washington, in improving irrigation district laws, and in securing wise legislation with respect to reclamation projects and the highest use of water and other natural resources. He was one of the founders of the Washington Natural Resources Association, served on its executive committee for a number of years, and eventually became a life member. He was a member of Sunnyside Lodge No. 138, A. F. and A. M., and of Sunnyside Chapter, R. A. M.

Those who knew Ross Tiffany intimately will cherish the memory of a true friend, the comradeship with a gentleman of fine character, and the association with a capable engineer who was genuinely devoted to the development and upbuilding of his state. He was one of the most highly respected and best loved engineers in the Pacific Northwest.

Mr. Tiffany has been active in the affairs of the Society since his election to membership in 1920. For five years he was a member of the Executive Committee of the Irrigation Division and during the last year of the period (1936) served as its chairman. He was President of the Tacoma Section in

1931 and was elected Director of the Society from District 12 in 1937. Only half of his term had been served when death intervened.

Mr. Tiffany was elected a Member of the American Society of Civil Engineers on October 11, 1920.

WARREN AYRES TYRRELL, M. Am. Soc. C. E.[1]

Died June 29, 1939

Warren Ayres Tyrrell, designing engineer of the Board of Water Supply, City of New York, N. Y., since 1927, had the valuable faculty of inspiring a loyalty and esprit de corps in his associates that made his designing section a coherent, efficient, and enthusiastic group. He was the drainage shaft expert of the Board of Water Supply and was the designer of the unique Shaft 9A of City Tunnel No. 2, a combined drainage and section-valve shaft at the foot of Steinway Street, Astoria, Long Island City, N. Y. He also had under supervision the design of the three drainage shafts for the new Delaware Aqueduct. Such responsibilities involved complete structures both above the ground level and deep down (about 700 ft) in the solid rock. The structures contain the intricate mechanical and electrical equipment necessary for un-watering many miles of sections (45 miles, 25 miles, and 15 miles) of the huge main water tunnel. So wide and varied was his engineering experience that when the position of mechanical engineer was left vacant by the death of Ray C. Ewry, Mr. Tyrrell was designated as acting mechanical engineer in addition to continuing his duties as designing engineer; he held both of these positions at the time of his death.

Mr. Tyrrell was born at Mexico, Mo., on February 16, 1875, the son of George J. Tyrrell, born in London, England, and Frances Shootman, of Mexico, Mo. He attended the elementary and high schools of St. Louis, Mo., and was graduated with the degree of Bachelor of Science in Civil Engineering from Washington University at St. Louis, *summa cum laude* in June of 1897. At Washington University, Mr. Tyrrell had the benefit of personal instruction under such well-known professional engineers as Henry S. Pritchett, C. M. Woodward, Francis E. Nipher, E. A. Engler, and the late J. B. Johnson, M. Am. Soc. C. E.[2] He had the experience of assisting Professor Johnson in the compilation of data for his classical treatise on "Strength of Engineering Materials," and of doing work in the United States Testing Laboratory at Washington University, of which Professor Johnson was in charge.

Because of the diversity and comprehensive character of his practical engineering experience for a period of more than forty years, it is desirable to itemize, briefly, the professional record of Mr. Tyrrell:

---

[1] Memoir prepared by Thomas K. A. Hendrick, Assoc. M. Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LI, December, 1903, p. 454.

October, 1897, to June, 1899—with the St. Louis, Peoria and Northern Railroad Company (the late Robert Moore,[3] Past-President, Am. Soc. C. E., chief engineer), as a levelman on the preliminary survey, as a topographer and transitman on the location survey, as assistant resident engineer on construction and maintenance, and as a mining surveyor for the Madison Coal Corporation (which was associated with the aforenamed railroad); in this work he was associated with the well-known engineer of St. Louis, Baxter L. Brown, M. Am. Soc. C. E.

June, 1899, to April, 1901—with the St. Louis Water Department as assistant engineer in the Extension Department—computing, designing, and drafting; later inspector and superintendent in the Distribution Department (in this work he was associated with Edward Flad, M. Am. Soc. C. E., of St. Louis).

April, 1901, to March, 1902—structural engineer for Christopher and Simpson, Architectural Iron and Foundry Company, designing, making shop drawings and shop inspections.

March, 1902, to March, 1903—with E. P. Maule, General Contractor, designing for Mauran, Russell and Crowell, Architects; designed the steel work and foundations for the 17-story annex to the Chemical Building in St. Louis, for which he made all the shop drawings, mill and shop inspections, and superintended the erection.

March, 1903, to March, 1914—general practice as a structural engineer in St. Louis. He designed for architects, estimated for contractors, and furnished shop drawings to steel companies. He designed the steelwork and foundations for many buildings, among which are the following: Fine Arts Building, University of Kansas, Lawrence, Kans.; Castner Knott Building, Nashville, Tenn.; Inter Southern Life Insurance Building, Louisville, Ky.; Grand-Leader Building, The Frisco Hospital, The Wall Office Building, Cement Plaster Mill for the Acme Cement Plaster Company, St. Louis, Mo.; and City Hall, Little Rock, Ark. Mr. Tyrrell represented such well-known firms as the Raymond Concrete Pile Company, Noelke-Richards Ironworks of Indianapolis, Ind., The American Bureau of Inspection and Tests, and the Cerosit Water-proofing Company. He was also consulting engineer for the Concessions and Admissions Department of the Louisiana Purchase Exposition Company, and inspector of boilers and elevators for the City of St. Louis for about one year. For his work with the St. Louis Exposition in 1904, Mr. Tyrrell received an engraved bronze medal which he prized very highly throughout the remainder of his life.

March, 1914, to September, 1914—Yellowstone Sulphur Company, Cody, Wyo. (W. F. B. Berger, Denver, Colo.), designing and superintending the erection of a mill for extracting sulfur from geyser deposits.

September, 1914, to June, 1917—with the Commercial Acid Company, East St. Louis, Ill., as construction engineer, and later in charge of office engineering on a large amount of chemical construction—chamber and contact sulfuric acid plants, boiler house, wedge roasting furnaces, sulfur burners, purification systems, etc.

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 1618.

June, 1917, to September, 1917—engaged in a series of studies of condensers for zinc vapor for the Metallurgical Laboratories, Incorporated, St. Louis, under C. H. Fulton of the Case School of Applied Science, Cleveland, Ohio.

November, 1917, to June, 1918—office engineer for J. H. Miller, Inc., general contractors, Baltimore, Md., in charge of matters pertaining to subcontractors on work for the United States Government.

June, 1918, to November, 1918—with the Air Nitrates Corporation, New York, N. Y., as assistant to the late Chauncey Grant Williams, M. Am. Soc. C. E., supervisor of purchases.

December, 1918, to October, 1923—with the J. G. White Engineering Corporation of New York City as resident engineer at the Nichols Copper Company at Laurel Hill, Long Island, N. Y., in which work he had varied engineering responsibilities.

October, 1923, to October, 1925—special studies and designs as office engineer for J. G. White Engineering Corporation on complicated structural problems.

November, 1925, to June, 1926—chief engineer and production manager for the Chemical Treatment Company, New York City, engaged in the developing process of electroplating with chromium. The company had plants in New York City, Waterbury, Conn., Chicago, Ill., and many licensees. Mr. Tyrrell was associated with John T. Pratt, L. C. Owens, and F. Hirchland.

July, 1926, to March, 1927—production manager of the Chromium Corporation of America, in New York City, which company was a combination of the Chemical Treatment Company and the Metal and Thermit Corporation.

Mr. Tyrrell's next assignment was with the Board of Water Supply, City of New York, as stated previously.

In addition to his superior ability as a technician, Warren Ayres Tyrrell possessed those qualities of mind and heart that endeared him to his associates (of whom the writer was one). There was always displayed a quiet, unobtrusive, friendly disposition which was extremely effective in promoting harmony among all cooperating engineers and engineering groups. He made a conscious effort to develop an atmosphere in which each individual felt that, while the very best was expected of him, he would be given three chances to make good. This was naturally conducive to a high degree of productivity.

Mr. Tyrrell had some characteristic sayings that he used advantageously and with discretion. He used to quote: "Today is the tomorrow we worried about yesterday, and it never came!" and "It is only by varied iterations that alien conceptions can be fostered in reluctant minds."

He was always ready for the job ahead; and this acted as a spur to stimulate curiosity in and complete the job at hand. A quiet affirmation was oftentimes his sole mark of insistence on orderly procedure. His high efficiency as an engineering executive was due partly to a regard for his associates as a team of engineering specialists, to each of whom certain phases of the analysis of a new problem were to be assigned. He had particular ability in dissecting a complicated design problem into its component parts and of making the most favorable distribution of these components to the engineers available best suited to analyze them. Although he encouraged such specialization, he was also careful to emphasize that the solutions to the various aspects of a problem must be coordinated and cleared into a unified practicable result. He would allow nothing to interfere with the accomplishment of this objective.

A familiar expression of Mr. Tyrrell, when considering a difficult analysis that had been carefully worked up and checked, was: "Can forty engineers be wrong?" Whereupon he would immediately exert a penetrating scrutiny bearing upon the assumptions made, the limitations of the materials used and their fabrication, the practical matters of economical construction, erection, and any other items pertinent to the problem at hand. He weighed those ideas of statute and common law, the exigency of which had directly or indirectly its effect and influence upon design and construction. With his clarity of vision, simplicity of statement, and informal manner of discussion, his ensuing analysis would not only indicate what changes had to be made, but, in general, would lead the way to the finally adopted solution, supported by the "over-the-table" discussions, the checked computations, and, in short, the concurrence of all minds. Certainly this was design leadership of a high order.

What was the basis of such leadership? Unquestionably it was bound up in the man himself. For each decision to be made, Mr. Tyrrell was always careful to inform himself thoroughly on the up-to-the-minute status of all relevant details. Visualization of facts was easy for him; indeed, his associates were often amazed at the clearness and scope of his descriptions. His keen insight always sought "to tie up loose ends" and to anticipate logical sequences envisaging the completed picture of the project as well as the detailed "close-ups" of progressive stages of the work. This close attention to specific detail was so natural to him that he continually elucidated intricate matters with a perspicacity that not only resulted in most excellent expression in clear-cut language, but also gradually established that high measure of inspiration which his associates continually felt in and out of his presence. The natural by-product accruing to his designing group was an increased efficiency in, and an entirely natural enthusiasm for, the work.

Since 1921, Mr. Tyrrell had resided at Merrick, Long Island, spending many winters in New York City. While living in Merrick, he took an interest in its many activities, being for several years a member of the Board of Education, a member of the Advisory Board of the First National Bank of Merrick, and a member of the Board of Trustees of the Merrick Library. At the time of his death, he was President of the Merrick Club, a club devoted to tennis and outdoor sports.

He is survived by his widow, the former Flora B. Hess of St. Louis to whom he was married on June 16, 1909, and a son, Warren Ayres Tyrrell, Jr. Mr. Tyrrell was of the Episcopalian faith.

Mr. Tyrrell was elected a Junior of the American Society of Civil Engineers on October 2, 1900; an Associate Member on October 1, 1902; and a Member on June 16, 1924. He was elected to Life Membership in 1937, and the warmth and depth of his appreciation manifested itself quietly in recurring expressions of the value of the honor bestowed.

AUBREY WEYMOUTH, M. Am. Soc. C. E.[1]

DIED JULY 27, 1939

Aubrey Weymouth was born in Richmond, Va., on November 18, 1872, the son of Edgar Jenkins and Medora (Strode) Weymouth. His parents were of Old Dominion stock.

Mr. Weymouth prepared for college at Kenmore in Amherst, Va. He entered Lehigh University, at Bethlehem, Pa., in September, 1890, and was graduated with the degree of Civil Engineer in June, 1894. He was an honor student in college and also had time for an important part in student activities. He was on the editorial board of the college paper for three years, historian of his class in his sophomore year, and was a member of many student bodies. He displayed a spirit of gentle merriment tempered by dignity and a sturdy character throughout his undergraduate days. These qualities persisted throughout his life and made his undertakings enjoyable to his associates despite the weight of some of them.

Mr. Weymouth spent most of his professional life in building construction. He witnessed the beginning and entire development of the skeleton-frame tall building, and personally took a very important part in the execution of this development. The skeleton-frame building satisfied an urgent economical need in New York, N. Y., and fortunately foundation conditions there are such that they permitted the remarkable development that has occurred.

Mr. Weymouth's first position, as draftsman for Bureau of Yards and Docks, United States Navy, at Port Royal, S. C., lasted for one and one-half years after his graduation from college. In April, 1896, he was employed by Purdy and Henderson, engineers, who specialized and pioneered in the design of steel skeleton frames for buildings.

After one year as draftsman he resigned to enter the employ of Post and McCord. From April, 1897, to April, 1900, the period of his first employment with Post and McCord, he worked on shop drawings and checked the shop drawings of other draftsmen for the steel framework of buildings. In this work he showed great ingenuity and resourcefulness. One of the notable buildings of the time on which Mr. Weymouth worked and took an important part in the preparation of its structural steel drawings was the Washington Life Building of New York City.

---

[1] Memoir prepared by Clarence W. Hudson, M. Am. Soc. C. E.

In April, 1900, Mr. Weymouth was employed by the American Bridge Company, of New York City. He remained with them until January, 1904. For the first part of this period—1900 and 1901—he was in charge of drawings for the Mt. Sinai Hospital buildings and the Corn Exchange Bank, both of New York City; and for the second part—1902 and 1903—he was assistant engineer of the American Bridge Company's Brooklyn plant, while (along with other structural steelwork) the 58th Street Power House of the Interborough Company was being fabricated.

These early experiences with Purdy and Henderson, Post and McCord, and the American Bridge Company gave Mr. Weymouth an insight into the enormous growth of both total tonnage and size of individual members that was taking place in the steel skeleton frame for buildings. He became familiar with the coincident problems of detailing, fabricating, and erecting the frames that had to be solved before the building could be constructed economically and efficiently.

The foregoing experiences and his college training had fitted Mr. Weymouth for the important part he was to take in the future growth of the firm of Post and McCord when he was re-employed by them in January, 1904, as chief draftsman.

He became chief engineer in 1910, and vice-president and chief engineer in 1930. As chief engineer from 1910 to his last illness, which began in September, 1938, he was in charge of engineering in connection with furnishing and erecting the steelwork for hundreds of important buildings in New York City and the surrounding country. A detailed list of these undertakings would be interesting and would show fully the extent of Mr. Weymouth's professional contribution to building construction. However, a short but truly important list will be substituted for it: In New York City—the Metropolitan Tower, erected while Mr. Weymouth was chief draftsman; the Bankers Trust Building, Wall and Nassau Streets; Columbia-Presbyterian Medical Center; Hell Gate Power Station; Aeolian Hall; Barclay-Vesey Telephone Building; Savoy Hotel; Chase National Bank Building at Cedar, Pine, and Nassau streets; Western Union Building; Chrysler Building; Irving Trust Building at No. 1 Wall Street; several buildings for Metropolitan Square Development; Empire State Building; and several Rockefeller Center Buildings, the largest of which is the RCA Building. Also worthy of a place in this list is the New York State National Bank Building, at Albany, N. Y. Many of the buildings listed here were unprecedented in size when undertaken and had to be erected in a metropolitan area, the facilities, safety, and conveniences of which could not be impaired during erection. Mr. Weymouth's courage, serenity of disposition, upright character, and great physical strength were all necessary to enable him to do his part in the undertakings of the Post and McCord Company.

The words of R. C. Post of the Post and McCord Company will show how he was regarded by his associates in the firm:

> "Aubrey was loved and respected by every member of the organization.
>
> "His calm, logical judgment, his keen ability to discern the flaws in any situation under discussion, his honesty and fairness and his fine

> sense of the fitness of things were a source of pride and respect throughout the entire organization.
>
> "Men of his kind are rare, indeed, and his loss as a friend and valued associate will be deeply felt over the years to come."

In order to appreciate better the kind of man Aubrey Weymouth was, an account of some of his activities outside of his regular employment must be considered. Because of professional fitness, good judgment, and his ability to do constructive work when laboring with others he served on many bodies and committees working for the general good of his profession, the industry in which he was employed, and on city and state agencies for promoting sound construction and fair labor relations.

The following partial list of Mr. Weymouth's outside professional, business, and civic services may be considered representative:

For the American Institute of Steel Construction, he was Chairman of its Committee on Technical Research, a member of the Wind Bracing Committee, a member of the Technical Advisory Board, and a member of the Committee on Code of Standard Practice.

For the American Welding Society, he was a member of its Committee on Building Codes and of its Committee on Structural Steel Welding. He served on the Welding Research Committee of The Engineering Foundation.

For the Merchants Association, he served on the Committee on Building Laws and Regulations and on a Sub-Committee on Steel. He was a member of the City-Wide Building Department Committee of New York City.

For the American Standards Association he was a member of a Sub-Committee of the Sectional Committee A-57 on Building Requirements for Iron and Steel.

He was a member of a Special Advisory Committee to the Industrial Board, New York State Department of Labor, on State Standard Building Code.

He was vice-president of the Board of Governors of a New York Building Congress.

He served on a Joint Committee on Structural Safety in Building, which committee was organized by the Architectural and Engineering Societies of the New York Metropolitan District.

He was a member of several committees for both the Iron League of New York City and the Structural Steel Board of Trade.

Of the numerous outside interests in which Mr. Weymouth engaged, none showed the kindliness and generosity of his nature more than his work for his Alma Mater. He took a great interest in everything that pertained to her welfare. He was a strong supporter of the New York Lehigh Club over a period of thirty years. He helped in the incorporation of the Alumni Association and was an important factor in shaping its policies. He realized the part athletics and good living conditions play in a proper development of student education and character, and worked intelligently and fruitfully for clean, honest sport and for the establishment of a real college dormitory and living system on the campus. He was elected an Alumnus Trustee of the University in 1922, and on the expiration of this term, in 1928, he was elected a Corporate

Trustee and in this capacity served until his death. The executive officers of the University leaned heavily on him and had the greatest confidence in his sane judgment. For a number of years he was a member of the Executive Committee of the Board of Trustees. Mr. Weymouth never missed a meeting of the Board of Trustees until his last illness overtook him. Lehigh University conferred the honorary degree of Doctor of Engineering on him in 1935.

Although Mr. Weymouth was able to, and did, greatly enjoy his professional work and his outside activities he loved to get away from it all at times and play. He was an ardent and good golfer and one of his greatest pleasures was to get out on the links with groups of his friends, former college mates, and business and professional associates. Those who were fortunate enough to have had a day's play and recreation with him always came away refreshed and inspired by his spirit of fun and sportsmanship.

Mr. Weymouth was a member of the Pomonok Country Club of Flushing, N. Y., and of the Engineers Club of New York City.

On April 27, 1901, in New York City, he was married to Alice Buer White of Beaufort, S. C., a member of a well-known family of the state.

Mr. Weymouth's first serious illness was in the spring of 1938. However, aided by his great courage he was able to " carry on " until September of that year, after which time he was confined to his home until his death.

He is survived by his widow, and his two daughters, Mrs. A. Hawley Peterson (Medora Weymouth) and Mrs. Russell H. Moock (Martha Weymouth).

Mr. Weymouth was elected a Member of the American Society of Civil Engineers on May 2, 1911.

FRANK WILCOX, M. Am. Soc. C. E.[1]

DIED MAY 25, 1939

Frank Wilcox was born on May 26, 1854, in the old City of Allegheny, Pa., at the site of the present North Side Post Office. He was the son of Lemuel North Wilcox and Eliza Fleming, of English and Irish ancestry.

He received his early education at the old 4th Ward School in Pittsburgh, Pa., later attending Stevens Institute of Technology at Hoboken, N. J. He was graduated with honors in the class of 1880, receiving the degree of Mechanical Engineer.

Upon graduation he associated himself with his brother John in the foundry and machine business in Pittsburgh, the firm being known as Wilcox, Shinkle and Miller. It was in this shop that the first Bessemer Converter was built for the Edgar Thompson Steel Company at Braddock, Pa.

Mr. Wilcox severed his connections with this firm in 1884 to become engineer of the newly organized Peoples Natural Gas Company, and laid the first gas line from the Murraysville Field into the City of Pittsburgh. When the late George Westinghouse, M. Am. Soc. C. E., organized the Philadelphia Company, Mr. Wilcox became engineer, and reported to T. A. Gillespie, who was then general superintendent in charge of construction for Mr. Westinghouse.

---

[1] Memoir prepared by W. C. Hawley, Alfred C. Ackenhell, and Charles L. Fox, Members, Am. Soc. C. E. W. C. Hawley died December 10, 1939.

During this time Mr. Wilcox laid numerous gas pipe lines into various glass houses, iron mills, furnaces, and manufacturing plants in the City of Pittsburgh. When the Philadelphia Company became firmly established, Mr. Wilcox resigned to become superintendent of the Pittsburgh Water Department, and under his supervision were constructed the Brilliant Pumping Station and Highland Park Reservoir.

In 1890 the firm of T. A. and R. G. Gillespie was formed for the construction of large riveted steel pipe lines, and it was at this time that Mr. Wilcox joined the Gillespie Brothers in what proved to be his life work—the construction of pipe lines for gas, water, and air.

Later when the T. A. Gillespie Company was organized, Mr. Wilcox became chief engineer of that large contracting company, and remained with Mr. Gillespie until 1916, when he retired from active duties, but continued his connection with the company as consulting engineer.

His experience with the Gillespie Company was wide and varied, and included the construction in 1895 of one of the first steel water lines in the United States—a 60-in. riveted steel line for water supply to the old City of Allegheny, water lines for the Board of Water Supply for New York and Rochester, N. Y., Jersey City and Atlantic City, N. J., and Detroit, Bay City, and Saginaw, Mich. During his engagement with the Gillespies he built locks and dams, tunnels, and railroads for thirty years.

In the early days of the natural gas business, he was looked upon as an authority in that field; in the introduction of steel pipe lines he stood preeminent as a pioneer; and his advice on design, manufacture, and installation was eagerly sought.

Thomas H. Gillespie, President of the T. A. Gillespie Company, writes of Mr. Wilcox as follows:

> "He was a most lovable character, generous in the extreme, and with a wealth of knowledge and experience, always at the disposal of his associates, and he performed a task as pioneer in the pipe line field that will be long remembered."

All who came in contact with Mr. Wilcox during the many years of his active professional life will agree with this statement.

On November 10, 1886, he was married to Mary Ann Brett of Brookline, Mass. She died in 1929.

Mr. Wilcox died on May 25, 1939, at Mt. Carmel Hospital in Columbus, Ohio, following a two weeks' illness which resulted from a fall on the porch of his home. He is survived by his brother, Charles Wilcox; a son, Winthrop; and a granddaughter, Nancy Wilcox. Mr. Wilcox was a valued member of the Society and his passing will be a distinct loss.

Mr. Wilcox was elected a Member of the American Society of Civil Engineers on October 7, 1903.

SYDNEY BACON WILLIAMSON, M. Am. Soc. C. E.[1]

DIED JANUARY 13, 1939

The Williamson family is of English ancestry and the name is found in various localities of Great Britain. The first of the name to come to Virginia was John Williamson, a native of Kent, who landed on this side of the water in 1707 and settled in Norfolk County, Virginia. His great grandson was Thomas Hoomes Williamson, born in Richmond, Va., on August 13, 1813, and the father of Sydney Williamson.

Thomas Williamson, after early schooling in Norfolk, Va., entered the United States Military Academy at West Point, N. Y., in 1829. He remained nearly four years, but he did not graduate. Adopting civil engineering as a profession, he was engaged in various important railroad and canal works in his native state until 1841. He then accepted a position as instructor of tactics and drawing at the Virginia Military Institute at Lexington, Va., within two years of the founding of this famous school. For forty-seven years he labored here, becoming later not only professor of engineering, but also filling the chairs of drawing and architecture. He also served a 4-yr period as commandant of cadets and another like one as treasurer. During these years he exerted a memorable influence on the hundreds of young men he taught and contributed importantly toward building up an esprit that has made the Institute world famous.

During the Civil War, although 48 years old, he took "time out" to volunteer his services to Virginia, and was appointed a Lieutenant-Colonel of Engineers, C. S. A., serving first as Chief Engineer of the Army of the Potomac at the First Battle of Manassas. He was cited by his commander, General Beauregard, for discharging his duties, which consisted of laying out the lines and field works at Manassas and Centerville, "with untiring energy and devotion, as well as satisfactory skill." He served throughout the war, and it is recorded among other items that he located the batteries along the Potomac and Rappahannock rivers, laid out the defensive lines at Fredericksburg, Va., and was asked for specially by General "Stonewall" Jackson to serve as his Chief Engineer during the McDowell phase of the famous Valley Campaign of 1862. Later he received the honorary rank of General and was so called for the rest of his life.

General Williamson married twice. His second wife was Julia Anna (Lewis) Wharton, whose forbears of Scotch-Irish stock were among the early settlers of Rockbridge County, Virginia. Their son, Sydney Bacon Williamson, was born on April 15, 1865, in Lexington, and was destined to become one of the great engineers of his generation. As his career unfolds, it is easy to trace the influence exerted by his father and by the sterling qualities derived from his ancestry.

---

[1] Memoir prepared by Col. George R. Goethals, U. S. Army (*Retired*), New York, N. Y.

To be reared in such an atmosphere as Lexington must have been inspiring to any boy. Sydney was born in a house at the end of South Randolph Street, which was in sight of the grave of "Stonewall" Jackson in the adjoining Presbyterian Cemetery. Thomas Jackson and Thomas Williamson had been old friends and fellow professors at the Institute, and from the father the boy would hear many tales of the famed Confederate leader. The dignified and beloved figure, Gen. Robert E. Lee, president of Washington College (later Washington and Lee University), at Lexington, in Sydney's earliest years, left an impression that was well remembered as the boy passed on to manhood. Gen. Sam Houston was born only 7 miles away, and many others who became nationally famous in diverse fields were either natives of Lexington or claimed the town as home. Sydney first attended the school conducted by Gen. William N. Pendleton, formerly General Lee's chief of artillery, and his daughter at the Episcopal Rectory, in an atmosphere of inspirational refinement and educational efficiency. Then he entered the public high school of Lexington and was taught by Capt. J. H. B. Jones, famous as leader of one of the few company units to reach Cemetery Ridge in Pickett's immortal charge at Gettysburg. Jones was as good a mathematician as soldier, and to him Sydney owed the fine grounding which he applied so well during his later engineering career.

When only 15 years old, Sydney qualified to enter the Virginia Military Institute, from which he was graduated in June, 1884. A fellow cadet, Capt. Greenlee D. Letcher, of Lexington, reports him as very popular, a fine baseball and football player, a beautiful skater and dancer, with a most delightful personality. In the battalion organization he was cadet adjutant. He belonged to Kappa Alpha fraternity (southern). His standing at graduation was ninth in a class of eighteen. In his own words, "this was mediocre, but I derived some consolation from theory that the hard students stood at the top of the classes, the stupid ones at the foot, and the bright students in the middle."[2]

After graduation, through the influence of his roommate, he accepted an offer as instructor in "Belles Lettres and Commandant of Cadets at the King's Mountain Academy at York, S. C.,"[2] and began his duties in September, 1884. Here he remained for nearly two terms, until February, 1886, when a letter arrived from a classmate urging him to join the former in business at St. Paul, Minn. So he resigned from Kings Mountain Academy, whimsically recording later, "I thought I did well as commandant but not so well as teacher."[2]

On his arrival in St. Paul, the greeting from Camden was disappointing: there was no job, so he had to take whatever he could get, and that quickly. After a few weeks with a real-estate dealer, he was "fired" for refusing to perform menial family tasks for his employer. A few days with an old land surveyor, and, for failing to "prick off" some plots of land tracts to the satisfaction of his boss, he was "fired" again—"fortunately," he records, "because it was then that I really made a start in my chosen profession."[2]

---

[2] From longhand manuscript by Colonel Williamson, in possession of the Williamson family, entitled "Record of Incidents Professional and Otherwise," dated January 16, 1934.

This start was a short assignment of three months from the resident engineer of the Chicago, Burlington and Quincy Railroad Company to compute quantities on a line recently surveyed. From this position he was secured in July, 1886, by C. A. F. Morris, chief engineer of the former St. Paul and Duluth Railway. Here he served as transitman on the relocation of this line from Thompson, Minn., to Duluth, Minn., a survey performed in a bitter winter; then he was in charge of a 10-mile, and soon after a 20-mile, residency; finally he became principal assistant to Mr. Morris on several proposed changes, notably between St. Paul and White Bear Lake, Minn. While on his residency he was much impressed by a visit and inspection by the late James J. Hill,[3] Fellow, Am. Soc. C. E., to whom Mr. Morris introduced him as the engineer in charge.

> "Mr. Hill said, 'Well, young man, I do not want any trestles on that line—only a solid roadway.' After leaving, I asked Mr. Morris what Mr. Hill had to do with it, and he said that Hill only owned about 52%, which was enough for him to dictate as to what he wanted. The road was built as Mr. Hill specified with stone culverts and fills. I think it was the heaviest piece of railroad construction in Minnesota at that time * * *."[2]

When surveys for the proposed changes were completed, a new control came into power, opposed further spending, and, as 1889 began, Mr. Williamson had to seek another job. He found it with the Northern Pacific Railway Company and became assistant to Mr. Kendrick, the chief engineer. He went to Billings, Mont., to look after a 50-mile branch line headed for Cooke City, Mont., from Rocky Fork through Laurel, Mont., and surveyed an alternate route from Cooke City to join the main line via Stillwater Canyon. Later he returned to St. Paul and made an important reconnaissance through northern Minnesota over practically the line later occupied by the Great Northern Railway. After preparing a general map of the country traversed, he received an offer from Montgomery, Ala., too attractive to refuse, and, at the close of 1889, resigned from his railroad work to accept membership in the firm of Williamson and Earl.

His older half brother, the late W. G. Williamson,[4] M. Am. Soc. C. E., had recently resigned as city engineer of Montgomery and had formed the firm of designing engineers bearing his name. After Sydney joined, among their retainers were the design and construction supervision of sewerage systems for several towns, among them Columbus, Ga.; plans and supervision for paving of certain Montgomery streets; and grading for the Capitol grounds. When work slackened in 1891, W. G. Williamson took a position as U. S. assistant engineer on the Tennessee River at Milton's Bluff, Tenn., and soon after (in September) employed Sydney as a transitman to make surveys of all river improvements then contemplated between Milton's Bluff and Decatur, Ala. In due course, the latter was advanced through various ratings and also became assistant engineer. The young Lieutenant of the Corps of Engineers in charge of the district which then comprised all river work below Chattanooga, Tenn., was the late George W. Goethals,[5] M. Am. Soc. C. E. From this mutual assignment arose a friendship never broken and a professional contact extended over many years, which was often interrupted by the turn of fortune, only to be resumed time after time.

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXI (December, 1917), p. 1829.

[4] For memoir, *loc. cit.*, Vol. XLI (June, 1899), p. 645.

Mr. Williamson was soon sent to the district office in Florence, Ala., to take important part on plans and estimates for the lock nearby at Riverton, Ala., designed to by-pass Colbert Shoals, Ala. The design for this lock has historical significance, in that its extreme low-water lift of 26.42 ft was the greatest to be attempted anywhere up to that time. In fact, the district engineer encountered no little opposition in getting the original scheme, for two locks of 13-ft lift each, set aside in his chief's office in Washington, D. C. However, the single lock was finally approved, and with two exceptions[6] remained the highest lift lock in the world until those at Panama were built.

The construction conditions encountered were no less difficult than the design was radical. As Mr. Williamson describes it,

> "The lock site * * * was close to the south bank of the river and the soil consisted of a few feet of loam underlayed by quicksand, and several unsuccessful efforts had been made to sink a shaft through the quicksand to determine the depth to rock foundation. Lieut. Goethals sent me to Riverton to try my hand at getting down to rock. We made heavily braced boxes seven feet square by about six feet long and sunk these as far as they would go or could be driven, which was about ten feet below the surface. From that point down Wakefield sheet piling was used by driving it a few feet at a time by hand, then excavating and bracing over that distance and repeating the operation of driving, excavating and bracing until we reached rock at about 25 feet below the surface. The foundation of the lock was fixed a few feet below this, so we drilled down about 25 feet into the rock to ascertain if it was bedrock or merely a thin stratum, then put in a light shot to get samples. The quicksand exerted great pressure on bracing of our forms and they cracked now and then and additional bracing had to be put in quite frequently. All this frightened the men doing the excavation and I had to stay down in the pit with them to watch the bracing and allay their fears. The labor was darkies except there was one white man named Jim Smith and Jim was a most cheerful liar. When we were loading the hole in the bottom of the pit to shoot out samples the men began to speculate as to what would happen if the dynamite went off prematurely. There wasn't much doubt in my mind. Jim helped the situation by telling of being in a well when the dynamite went off. He said, 'Me and two other niggers were blasting down in a well once when the dynamite exploded and blew them niggers all to pieces.' I asked him, 'what did you do, Jim?' His reply was, 'Oh, I just stepped aside and let her go by.'"[2]

The district engineer inspected one day while Mr. Williamson was with his men at the bottom of the pit, and "from that moment until the day of his death Goethals had Williamson as his lieutenant on every job of importance."[7]

The subsequent construction history saw the contractor fail after incompetent performance and before any masonry was laid. The work then was put on a force account basis with Mr. Williamson in direct charge and thereafter proceeded to successful and uneventful conclusion.

---

[5] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1813.

[6] Lock between Mississippi River and Bayou Plaquemine, lift 37 ft, begun in 1895; and Hales Bar Lock, Tennessee River, lift 37.5 ft, begun in 1905.

[7] "Goethals: Genius of the Panama Canal," by J. B. and F. Bishop, p. 69.

In 1896, when the Riverton Lock was 75% completed, Mr. Williamson was relieved and put in charge of operation and maintenance of the Muscle Shoals Canal. While living on this assignment at Lock 6, he conducted an important series of field tests aimed to check the actual stresses developed in the lock gates against those deduced from the design formulas employed.

When the Spanish War began in 1898, he obtained a leave for the duration and accepted a commission as Captain in the Third Volunteer Engineers. He never served with this organization, for Goethals had applied for him as an assistant, and his service became identified with the staff of the First Army Corps under Maj. Gen. John R. Brooke in Puerto Rico. (After transfer from the Tennessee River in 1894 to the office of chief of engineers, Goethals had become Lieutenant Colonel, U. S. Volunteer Engineers, and Chief Engineer, First Army Corps, during the Spanish War.) Joining the command at Arroyo, Puerto Rico, his first task was the construction of a dock for lighters to land troops and supplies from transports lying out in the practically open roadstead. Soon after, the hope for active campaigning was shattered, for just as General Brooke's command was about to go into action to open the road to San Juan, Puerto Rico, a dispatch announcing the signing of an armistice arrived. Thereafter, the work that fell to Captain Williamson was confined to making the San Juan highway passable by repairing the arch bridges blown up by the Spaniards and removing stone slides which they had blown down across the road in many places. His request to be sent home was then immediately approved, and he left the island without even visiting San Juan, which his efforts had again made accessible. He resumed his former duties on the Tennessee River, with assignment to the Chattanooga office.

In August of 1901, Mr. Williamson was transferred (still as U. S. assistant engineer and again on the application of Major Goethals, then district engineer at Newport, R. I.) to Newport, at that time headquarters of the U. S. Engineer District comprising all federal river and harbor work between Block Island, R. I., and Nantucket, Mass. The most important projects then under way consisted of the new sea-coast defenses of Narragansett Bay and modernization of existing forts. Mr. Williamson was in charge of building the emplacements since embraced in the tactical groups comprising Forts Greble and Getty. Up to that time much trouble had existed, because of the climate of this latitude, in keeping the powder magazines dry. Built of massive concrete, the walls and ceilings used literally to run with moisture caused by condensation induced through the variable humidities and temperatures, not only as between winter and summer, but often as between night and day. A practical solution was found by building an inner room of hollow, porous tile, with narrow air space between its walls and the outer concrete, and a like space between its false tile ceiling and the concrete roof; as fast as condensation against the concrete took place, it drained off through the air spaces, while the tile acted as a blotter, absorbing the moisture in the air of the magazine, draining it off to the air spaces when saturated, and maintaining proper conditions for the storage of powder. Mr. Williamson collaborated in developing this important innovation, and the method came into general use in fortifications located in comparable climates.

With the completion of the new forts, work slowed down to dull routine in the Newport district. Mr. Williamson had been studying with keen interest the rapidly growing use of reinforced concrete, and in the latter part of 1903, after twelve years of unbroken government service, he resigned to become engineer with the Expanded Metal Engineering Company of New York, N. Y. This brought close contact with the Corrugated Bar Company of St. Louis, Mo., for which he shortly went to Baltimore, Md., making his headquarters there right after the big fire. This was the era when few engineers, and fewer architects, were familiar with reinforced-concrete design, and companies handling reinforcing materials were guarding their formulas carefully. Mr. Williamson not only secured work in Baltimore but also in Norfolk, where building opportunities anticipating the Jamestown (Va.) Exposition were very active. In many cases, where structural steel had been specified, Mr. Williamson would persuade the architect to allow an alternate in reinforced concrete. While this compelled the former to prepare his own structural design and estimate, it secured him even more buildings, a number of highway bridges and culverts, a pier at the Jamestown Exposition, and the 14th Street car barn (street railway) in Washington. This activity continued until May, 1907.

Down in the Canal Zone, President Theodore Roosevelt had placed a new Commission in charge of the work, the chairman and chief engineer of which was Mr. Williamson's former chief of Riverton, Puerto Rico, and Newport days. While his private work in Baltimore had been successful and profitable, Mr. Williamson felt he could not refuse the engineering opportunities afforded by the offer Colonel Goethals made him, although, when he reached Cristobal, Canal Zone, on May 17, he had no idea of the important position to which eventually he was to be assigned. That he never regretted the change is shown later by his own words written in 1934 as he looked back on his long career: "All I can say is that it was the most interesting and absorbing piece of engineering I have ever been connected with."[2]

After sufficient opportunity to become thoroughly acquainted with the entire project, Mr. Williamson was first assigned in July as division engineer of La Boca (changed to "Balboa" on April 30, 1909) Lock Construction Division. In December his duties were expanded to include what was then termed the Pacific Locks and Dams Construction Division. He reported at this time to the late Maj. W. L. Sibert,[8] M. Am. Soc. C. E., one of the commissioners, then in charge of all lock and dam work.

On July 1, 1908, the whole canal work began to undergo a complete reorganization which was "brought about gradually through the year with a view * * * to concentrate authority, to expedite the transaction of business, to secure better coordination, to fix more definitely responsibility in any particular case, and to reduce the cost of administration."[9] Out of this reorganization arose the three construction divisions. The Atlantic and the Central divisions were each headed by Army engineers (who, incidentally, were also commissioners). It was Colonel Goethals' plan to have one of the divisions headed by a civilian, not a commissioner, with civilian subordinates. He accomplished this plan on July 15, 1908, by combining the old La Boca Dredging and the Pacific Locks and Dams divisions into the new Pacific Division, extending from mile 39.53 to deep water in the Pacific Ocean, a distance of 11 miles. Mr. Williamson was appointed division engineer, and thereafter reported, as did the other division heads, directly to the chief engineer. Without question the record of the Pacific Division of the Panama Canal was the great achievement of his whole professional career, as it combined all the elements of engineering, construction, and administration over a period of four and a half years, and brought to a peak those qualities which made him a leader in each.

[8] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1642.

[9] Annual Report of Isthmian Canal Commission for 1909, p. 1.

How Mr. Williamson organized and completed his assignment through the medium of five subordinate districts has become engineering history that is best presented in his own clear reports and writings.[10] It is pertinent to review here only certain aspects and recollections of the work which emphasize the value of his services.

The original plans of the Canal, set down by the minority members of the Board of Consulting Engineers (the Board appointed by President Theodore Roosevelt on June 24, 1905, whose minority advocated a lock canal—which minority report was adopted by the President), called for a flight of two locks at La Boca and one at Pedro Miguel. Later investigation proved the La Boca site undesirable, not only for military reasons, but because of the unsatisfactory foundation conditions developed for the proposed Sosa-Corozal Dam, a structure required if locks were placed at La Boca. A careful re-examination of the Canal route from Pedro Miguel to the Pacific was undertaken by wash- and diamond-drill borings, and by test pits. Mr. Williamson took direct charge of this investigation soon after it was started, the result of which was to confirm the decision to build a single lift at Pedro Miguel, whereas the La Boca locks were to be moved inland to Miraflores. Aside from the military advantage, the latter location brought about required dams of lower height, shorter length, better foundations, and earlier completion than would have been possible at La Boca. It would have been possible even to locate all three Pacific locks at Miraflores; but if they had been thus located, the foundations of the lower locks there would have had to be carried to a greater depth than was justified economically, and international conditions were bringing increasing clamor for earliest possible completion. Accordingly, arguments favoring lower operating costs for three locks in one place were overruled. Mr. Williamson's foresight and grasp of the essential factors leading to the Miraflores two-lock decision cannot be praised too highly.

The designs common to all the locks and other structures—the lock wall sections and culverts, the gates, the operating and safety machinery, types of buildings, quarters, and the like—were all handled in the office of the chief engineer at Culebra. Questions of design to satisfy conditions peculiar to each division, however, were delegated to the division engineer to draw up and submit for approval. Although Mr. Williamson was primarily the outdoor construction man, he originated many of the features developed in the Pacific Division by his very competent designing staff, improved the details of others, and kept in general touch with all. He would state what he wanted to accomplish, but usually let the designer find the best means. He was always open to suggestion and would insist on his own solution of a problem only when convinced it was better than another. After a long day mostly spent tramping over his division, he might often be seen carrying home an envelop containing some design problem to occupy his evening hours at his quarters in Culebra.

---

[10] See Reports of the Division Engineer, Pacific Division, in Annual Reports of Isthmian Canal Commission for 1909 to 1912, inclusive; see also "Methods of Construction of the Locks, Dams and Regulating Works of the Pacific Division of the Panama Canal," by S. B. Williamson, *Transactions*, International Eng. Cong., 1915, Vol. I, p. 428 *et seq.*

Mr. Williamson contributed ideas for improving the wooden cantilever forms for lock concrete that his division made famous (the original idea is attributed to one of his designing engineers, A. P. Crary, who brought it from a previous job). He originated the idea for the hollow concrete cylinders, sunk open-caisson fashion in superimposed sections, as used for most of the foundations for the Balboa terminal piers and for the north approach wall of the Miraflores locks. Although they were not built until after he had left the Isthmus (excepting the initial dock), Mr. Williamson made the general layout of the piers and docks at Balboa which was later adopted in all essential features. He decided to remove a large amount of blue gum mud in the Canal prism—difficult and expensive to handle in the ordinary dry way—by hydraulic means; he not only reclaimed much waste swamp land, but actually sluiced uphill and deposited the material as core for earth-dam construction by flooding the borrow pit and placing his dredge pumps on floating platforms or barges. The use of hydraulic giants and lock bar pipe for dam construction was rather an innovation for those days. He guided the design for the reinforced concrete barges on which these dredge pumps were mounted. He was the moving spirit in developing the designs for the balanced berm and chamber cranes, used so successfully and economically for mixing and placing the lock concrete, with a foresight that enabled their later dismantling and re-erection for use at the Balboa coaling station. After investigating four possible sites, he selected Ancon Hill for a quarry and made a crusher installation that provided stone in two sizes for concrete—not only for the Pacific locks, but also for the dry dock, the terminals at Balboa and Cristobal, a portion of the east breakwater at Colon, and most of the fortifications, to mention only the more important structures. With all his administrative duties and acknowledged preference for the construction end of the work, his contribution to practical design was marked.

The Pacific Division record for concrete yardage and economy was unsurpassed on the Canal work. The greatest concrete output at any of the locks of the Canal in any one month was that of April, 1912, at Miraflores, when 97,735 cu yd, place measurement, were handled, an average of 3,759 cu yd each 8-hr working day of the month.[11] (The best 8-hr record of the plant, mixer measurement, was as high as 5,700 cu yd.) Comparative concrete unit costs must be read with a clear understanding of all the facts—otherwise they are misleading. Offhand, the difference between those of the Atlantic and Pacific divisions appears to lie just about in the higher cost of stone and sand indicated in the cost reports of the former. This alone makes comparison unfair to the Atlantic Division because the securing of stone and sand from points 20 and 30 miles (respectively) beyond Colon, with a rough sea haul involved, was dictated by interdepartmental considerations lying outside the Atlantic Division (such as the capacity of the Panama Railroad, had rock been hauled from the Pacific side), whereas the Pacific Division obtained its stone with a maximum rail haul of only 7 miles, and its sand after a 20-mile sea haul across water that is invariably calm. The unit-cost performances of the two divisions, therefore, should be compared on the basis of the components entirely within the control of each, such as cost of mixing and placing, reinforcements, forms, power consumption, maintenance of equipment, plant arbitrary, and divisional overhead. In these respects Mr. Williamson's records were unequaled elsewhere.[12]

---

[11] Canal Record, Vol. VI, No. 3, p. 22.

He had no special routine. Those who worked on the locks were sure to have a daily visit from him. Those on the dredging, municipal, and other work would see him less often, but every one welcomed his coming. He was always ready to discuss the work with the youngest foreman, and if the latter had a suggestion which would speed up operations, Mr. Williamson would at once make the suggestion effective, giving proper credit. He was quick to recognize merit in comparative inexperience and to promote accordingly. The superintendent in charge when the Pedro Miguel lock was completed was just out of college when the Pacific Division was organized. The spirit in the division was spontaneous. All pulled together to get the job done. In Mr. Williamson's own words:

> "I had an excellent organization on my Division and there were very few changes in those holding responsible positions throughout the work. All of the force took an intense interest in the work especially since the work in the Atlantic Division was very similar, and due to this there was more or less rivalry between the two divisions, each striving to beat the record of placing concrete in the locks of the other. The yardage placed was published each week in the Canal Record and kept the employees of each division on their toes."[2]

The close of 1912 saw the Pacific Division work in the Canal prism substantially completed, except for minor details. The installation of the lock machinery at all Canal locks was centralized in a special division under the chief engineer. Mr. Williamson had no desire to remain on the permanent operating organization, and an offer had reached him to re-enter private work. He resigned, effective December 12, 1912, and shortly sailed for England to become chief of construction for J. G. White and Company, Ltd., with office in London.

---

[12] See reports of the Chief Cost Accountant in Annual Reports of the Isthmian Canal Commission for the period 1911–1913.

The field of this company at the time was world-wide, and the construction work controlled from London included a power station and street railway at Pernambuco, Brazil; similar work at Buenos Aires, Argentina; and a water supply system for Genoa, Italy. It was essentially a remote-control method of administration, wherein the directing head had little opportunity for the intimate daily contact with his men that the Canal work had afforded; yet Mr. Williamson's associates of that time speak warmly of his ability and accomplishment in the brief period in which he served. His work was suddenly curtailed by the outbreak of the World War in 1914, and as English capital was largely involved in the projects under the London office, most of the work came to a halt. Mr. Williamson returned to the United States.

His ability as a construction administrator had attracted the attention of the Hon. Franklin K. Lane, Secretary of the Interior. Up to that time the U. S. Reclamation Service had been divided into a number of supervisory districts all administered separately by the director and chief engineer from Washington. On December 10, 1914, Mr. Williamson started to make a survey with a view to recommending a reorganization. His views were adopted and on June 15, 1915, Mr. Lane established an executive office in Denver, Colo., with Mr. Williamson as chief of construction. Thenceforth all matters relating to management and execution of the work in the field passed through the Denver office. All other detached offices (except that of supervisor of irrigation, which remained at Billings, Mont.) were incorporated there, as well as the departments of purchasing, disbursing, collections, and examination of accounts, thereby effecting many administrative economies. The chief of construction had direct charge of all employees engaged on construction, operation, and maintenance. All project managers and engineers reported to him, and in the fiscal year, 1915, there were 36 projects under way or in operation, divided among six major divisions. A central designing office was also included to standardize all structures on various projects. One of the most important features was the installation of a uniform system of cost keeping adapted from the one used on the Panama Canal. Mr. Williamson's talent and experience enabled him to accomplish these innovations and economies quickly, and they were all functioning smoothly by the end of the year.

Early in 1916, Guggenheim Brothers were seeking a man of considerable construction experience to handle their interests in Chile. At the request of Harry Guggenheim for a suggestion, General Goethals recommended Mr. Williamson unqualifiedly. The latter resigned from the U. S. Reclamation Service, and began his new duties in February, 1916, as construction engineer, with designation later changed to consulting civil engineer. This assignment occupied him for the next eight years, except for the leave of absence given him during the World War. After he had organized the designing engineering department in the New York office, much of his time was spent in Chile, both at Antofagasta, where the properties of the Chile Exploration Company were located, and at Sewell, the headquarters of the Braden Copper Company. He also spent some time at various other places where important structures were located.

It was work after his own heart. To it he brought men from the old Pacific Division in Panama and from the U. S. Reclamation Service. It involved all features of work from design through construction and the care and feeding of workmen in the field. In his period of service the copper output of the Chile Exploration Company was increased nearly two and a half times, featured by extension of several mine railroads; modernization of equipment; numerous plant extensions; construction of a 9-in. pipe line more than 60 miles long to bring potable water from Toconce to Chuquicamata, Chile; a large power station at Tocopilla, Chile; and modern townsites completely equipped with quarters, churches, hospital, schools, and welfare facilities. Versatility to meet emergency was well illustrated by Mr. Williamson at Chuquicamata. During the World War, no more structural steel could be shipped from the United States, so he immediately altered all plans and programs by changing every major structure to reinforced concrete. For the Braden Copper Company, the output was practically doubled. Featured by new crushers, smelters, and a long aerial tramway, this work included housing and employee welfare facilities as installed for the Chile Exploration Company.

When the United States entered the World War, Mr. Williamson planned his work as far ahead as foresight would permit, and, although then 53 years old, offered his services to the War Department. His employers generously gave him leave for the duration of the war. He was commissioned a Lieutenant-Colonel of Engineers on June 19, 1918, assigned to the 55th Regiment of Engineers, and reached France on July 16. The regiment was sent to Gièvres for work under the section engineer of the Intermediate Section (west), and when the Colonel of the 55th Regiment was relieved to go elsewhere, Colonel Williamson assumed command. Later, on September 22, he relieved Colonel Graves as section engineer, and his duties were soon extended to include the District of Paris. On November 4, he was promoted to the rank of full Colonel. Of the large amount of varied construction work required in the line of communications, the work at Gièvres was the largest single project, and of Colonel Williamson's part therein his immediate superior, Col. Ernest Graves, U. S. Army (*Retired*), notes:

> "The Gièvres project contemplated a depot capable of storing supplies for one million men for thirty days. Its design covered an area 2 miles wide and 6 miles long, and included 213 warehouses, 260 miles of railway track, a large refrigerating and ice plant, two remount depots, a camp hospital, a veterinary hospital, a gasoline distributing station, barracks, a water supply system, shops, roundhouses and motor parks.
>
> "As my assistant at Gièvres Colonel Williamson was the same efficient, capable engineer that he had always been. He was not only skilful and experienced but he was also a first rate executive. He was placed in charge of the Depot construction so that I could give my time to other work of the Intermediate Section (west). Later Colonel Williamson also helped me on this other work. When I was relieved as Section Engineer, there was no doubt that Colonel Williamson should be the one to take charge. This he did and did well. The construction of the Depot was carried on efficiently by Colonel Williamson in spite of continuous diffi-

culties in securing supplies of labor and material. When the Armistice was signed, 174 of the proposed 213 warehouses had been completed and 132 of the 260 miles of track had been laid."[13]

Following the Armistice, his territory was further broadened with activity devoted to road maintenance and buildings at the various centers where troops were concentrated prior to entraining for the ports of embarkation. Early in March, 1919, he was relieved by his old commanding officer, Brig.-Gen. E. L. Daley, M. Am. Soc. C. E., U. S. Army, of the 55th Engineers, who writes of him:

> "The War time service of Colonel Williamson was characterized by great energy and resourcefulness * * *. Hundreds of officers and thousands of soldiers recall the calm and reassuring manner with which he tirelessly met engineering emergency after engineering emergency during the trying days from July, 1918 to March, 1919. His contribution to the winning of the War was valuable beyond measure." [14]

He finally left France on March 9, 1919, and was honorably discharged from the service the day after reaching the United States, resuming at once his duties with Guggenheim Brothers to complete the projects already outlined.

In January, 1924, Colonel Williamson had finished the work he had agreed to undertake for the Guggenheim interests, and his contract with this firm terminated. For the next five years he engaged in private practice, forming a consulting engineering partnership with his son, Lee Hoomes Williamson, M. Am. Soc. C. E., with offices in Birmingham, Ala., and Charlottesville, Va. After reorganizing and finally liquidating a contracting company for a bank in the former city, his activities followed mainly water-supply design, valuations, and appearance as expert trial witness, with occasional retainers in other fields. Important among these assignments were reconstruction of the water supply for Pulaski, Va.; studies for increasing the supply of Front Royal and Lexington, Va.; valuation of the Roanoke, Va., water company plant; similar work for the town of Appalachia, Va.; valuation of Camp Lee, Va., and testimony in connection with the trial of the contractor who built it; design of filtration plant for Fredericksburg, Va.; and design and supervision of a sewage disposal plant for Blacksburg, Va. In addition to this work he also found time to assist General Goethals, in the latter's last undertaking, as consulting engineer on the Lake Worth Inlet project at Palm Beach, Fla. He designed the transit sheds, the rail connections, the water supply, and sewage disposal for this harbor development. When General Goethals' illness prevented his presence in Florida, Colonel Williamson proved his devotion by representing him on the job and closing up the work upon the General's death in 1928. The last piece of private work engaged in by either of these long-time friends found them associated.

In 1929, President Herbert Hoover, Hon. M. Am. Soc. C. E., called Colonel Williamson again to an important government service, this time as one of the three civilian members of the Interoceanic Canal Board, appointed to investigate the cost of building and maintaining a canal across Nicaragua, as well as the practicability and cost of providing additional locks and other facilities at Panama. He was actively engaged on this work from June 12 until the Board submitted its report on November 30, 1931,[15] making one inspection trip to Nicaragua and Panama and spending the remainder of the time in the Washington office of the Board. Of all the valuable work accomplished by this Board, Colonel Williamson's individual contributions comprised a study under the title, "Probable Future Traffic through the Panama and Nicaragua Canals,"[16] and a practical plan for converting the Panama Canal into a sea-level route without interruption of traffic;[17] yet his broad general experience was felt and appreciated throughout all the ramifications of the Board's work, from the office in Washington to the field organization conducting the surveys in Nicaragua.

---

[13] From a letter by Colonel Graves to the writer.

[14] From a letter by General Daley to the writer.

> "Due to his experience on the Panama Canal, Colonel Williamson was a logical choice for appointment to the Interoceanic Canal Board. He brought to the work of that Board a knowledge of canal construction possessed at that time by no other engineer in the United States. He was the only civilian member of the Board who was employed continuously on its work. The meritorious nature of his service is indicated by the fact that, upon completion of the Nicaragua Canal Survey, he was retained as a consultant (Principal Engineer) in the Office of the Chief of Engineers * * *. Too much cannot be said in praise of the thoroughness and accuracy of the engineering work of Colonel Williamson."[18]

For the remainder of his professional career, Colonel Williamson continued in the rating of head engineer, and as such was a member of the Board of Engineers for Rivers and Harbors, devoting a large part of his time to river, harbor, and flood-control work in general, and to the Mississippi River flood-control problem in particular. The remainder of his time was spent in connection with the government's case in litigation regarding railroad, highway, and utility crossings over the Bonnet Carré Floodway. This involved preparing a mass of detail on design and cost analyses of such crossings to enable him to testify at the court sessions held in New Orleans, La. His testimony was of great value in reaching equitable settlement of these cases.

In 1935 Colonel Williamson's health began to fail, and on April 30 he was retired under provision of the Civil Service Retirement Act. Of the more than fifty-one years of his professional career, nearly twenty-seven of them had been devoted to the service of his government. He returned to Lexington, Va., re-established the family home there, and passed the remainder of his days quietly in the picturesque town of his birth. A progressive heart ailment forbade further activity, although he enjoyed and encouraged visits and letters from old friends. Toward the end of 1938 his condition became alarming, and on January 13, 1939, he died in his seventy-fourth year.

---

[15] Rept. of U. S. Army Interoceanic Canal Board, H. R. Doc. No. 139, 72d Cong., 1st Session.

[16] *Loc. cit.*, Appendix C.

[17] *Loc. cit.*, Rept. of Governor of the Panama Canal, Part III.

[18] Col. Ernest Graves, U. S. Army (*Retired*), Chairman of Interoceanic Canal Board, by letter to the writer.

He is survived by his wife, the former Helen C. Davis, a native of St. Paul, Minn., to whom he was married on May 20, 1890; their two children, Lee Hoomes, and Julia Lewis Williamson (Mrs. Julian Smith), and six grandchildren.

Colonel Williamson was an Episcopalian. Besides the American Society of Civil Engineers, he also held membership in the American Society for Testing Materials, the Cosmos Club, and the Army and Navy Club, the latter two in Washington, D. C.

The Virginia Military Institute signalized his passing by a general order[19] summarizing and eulogizing his career. The Board of Visitors also passed a resolution of condolence. In keeping with his characteristic wish for simplicity and avoidance of display of any kind, the funeral was simple and non-military, but, until her distinguished son was buried in Lexington Cemetery on the afternoon of January 14, before a throng gathered in silent tribute, his alma mater kept flags at half-mast.

As an engineer, the outstanding characteristic of Colonel Williamson was breadth of gage. Qualities frequently noted separately in many of his profession were found in him in a combination that occurs but rarely. He possessed marked ability and originality in design, without losing sight of practical considerations and economy in the field wherein so many pure theorists stumble. He was the ideal construction manager, with principles of theory so well grounded that he never relied, as many so-called construction men do, on mere rule-of-thumb methods with which to meet the unexpected problem or field emergency. On all of his peace-time assignments the speed and economy of performance attained were outstanding; yet, in a military situation, where action and speed must rule economic considerations, his versatility could adapt his course instantly to the special demands. He was a born manager of men, getting along with them just as well as they worked for him, and it mattered not whether military discipline was at his elbow. On the civil work he headed, a discipline was there just the same, although the men were never made aware of it. There existed the spirit by which men worked for the job and for him at the same time, whether he was moving from board to board in the drafting room or calming a group of laborers working at the bottom of a test pit and afraid of a cave-in. His attitude toward superiors was just as successful. The younger, ex-line officer generals in France, who would so often send for him to demand, in their innocent ignorance, the "engineering miraculous" to complete something tomorrow, would end the interview with a laugh at Colonel Williamson's exposition of the "engineering possible" and their thanks at having the job done within the time limits of human endeavor, as it always was. In short, every one, civil or military, who ever worked over, with, or under him, and really learned to know him, reached the same appraisal of his well-rounded ability.

---

[19] General Orders No. 14, Virginia Military Inst., January 13, 1939.

He was about 5 ft 10 in. tall, medium complexion, slender but wiry build with erect military carriage, and always neat in dress and appearance. Colonel Williamson possessed a keen wit and sense of humor impossible to describe, and always had command of anecdote to illustrate a point, whether while inspecting his work or sitting as a member of some board. His face was said to resemble greatly that of his father, and, due to the rigorous outdoor life of most of his career, it early became deeply lined and furrowed, giving a very serious, even severe, expression—until he smiled. One of the stories that he loved to tell on himself is of a youngster in Newport, who, seeing him frequently pass by deep in thought about some problem he had not left behind at the office, one day mustered up enough courage to run out, grab him by the hand, look up, and ask, "Mister, what yer cryin' fer?"

Although he was essentially a man devoted to family and friends and shunned society for its own sake, he was the best kind of company in any gathering. He had no foibles and those of others aroused in him amused tolerance. About the only qualities to irritate him were conceit and self-importance, and then he could register a choice sarcasm. A young captain, earmarked by these traits, who had served under him briefly in France, was ordered for service in Paris with the War Damages Board after the Armistice, and told Colonel Williamson on his parting visit that he (the Captain) knew he was badly wanted, "because they were in a fix for good men." "Yes," said the Colonel, looking over the top of his glasses, "and they're going to be in a whole lot worse fix, judging by some of the men they're sending up there."

The Distinguished Service Medal for his work at the Gièvres Depot during the World War was one of the material honors accorded him, but the most signal one was the designation by the governor of the Panama Canal of his likeness to appear on the 30-cent postage stamp of the permanent issue of the Canal Zone (designated for release on April 15, 1940—Colonel Williamson's birthday). It is especially noteworthy in Colonel Williamson's case, for this honor has otherwise been reserved solely for certain of those who held the rank of commissioner during the construction period of the Canal.

No monuments can be greater than the structures he left behind him or the affection in the hearts of those who worked for and with him. Upon his death he was mourned by all these people, wherever found. From Panama, the scene of his greatest achievement, came the word: "There are many men still here who remember his kindly spirit and the tremendously hard work he performed * * *. Of memorials there can be no lack so long as this magnificent work, to the construction of which he contributed in so distinguished a manner, endures."[20]

Colonel Williamson was elected an Associate Member of the American Society of Civil Engineers on January 3, 1894, and a Member on December 2, 1896.

---

[20] Brig.-Gen. C. S. Ridley, Governor of the Panama Canal, by letter to Mrs. Williamson.

FREDERICK NEWTON WILLSON, M. Am. Soc. C. E.[1]

DIED NOVEMBER 15, 1939

Frederick Newton Willson, professor of graphics, emeritus, at Princeton University, at Princeton, N. J., was the son of Thomas Newton Willson and Mary Caroline (Evarts) Willson. He was a direct descendant of Col. John Willson, of the Virginia House of Burgesses, and of Tirzah Humphreys, a niece of Samuel Findley, fifth president of Princeton University.

Professor Willson was born in Brooklyn, N. Y., on December 23, 1855. In 1872 he was graduated from Troy Academy in Troy, N. Y., of which his father was the principal. Immediately after graduation he served for one year as assistant bookkeeper in the Troy City National Bank, entering Rensselaer Polytechnic Institute, at Troy, as a freshman in 1873. After the freshman year he left college to teach mathematics at Troy Academy for the school year 1874–1875, during the illness of his father. He then returned to Rensselaer and was graduated in 1879 with a degree of Civil Engineer.

He took a postgraduate course in psychology and philosophy under his friend, Daniel S. Gregory, president of Lake Forest University, at Lake Forest, Ill. Following his postgraduate year he became assistant foreign correspondent of Drexel, Morgan and Company of New York, N. Y. Early in the winter of 1880 he was called to the College of New Jersey (Princeton) by President James McCosh to organize courses in graphics as part of the John C. Green School of Science.

In 1883 he was made professor of descriptive geometry, stereotomy, and technical drawing, a post created for him in the John C. Green School of Science. In 1896 Princeton University conferred upon him the honorary degree of Master of Arts, and in 1905 his title was changed to professor of graphics.

In 1922 the Department of Graphics and Engineering Drawing was established in the Princeton Engineering School, and Professor Willson was called upon to take the chairmanship and organize the department.

He served as professor of graphics and chairman of the department until he retired from active service in June, 1923, completing nearly forty-three years of university teaching. The courses that he taught included descriptive geometry, stereotomy, technical drawing, kinematics, and machine design.

As a scholar in the field of graphical science, he was recognized as an eminent authority. He developed a collection of models which represented the surfaces with which his teaching was concerned that became a valued possession of the Princeton Engineering School. His well-known treatise on graphics, descriptive geometry, and mechanical drawing, first published in 1897 and entitled "Theoretical and Practical Graphics," was given immediate recognition as an outstanding work.

---

[1] Memoir prepared by Philip Kissam, Assoc. M. Am. Soc. C. E.

In his enthusiasm to utilize his writings he published excerpts from his book while he was still in the process of completing it. These excerpts, together with the book itself, constituted a series of eight texts on various phases of his subject. They are the following:

1. Note-Taking, Dimensioning, and Lettering.
2. The Third Angle Method of Making Working Drawings.
3. Some Mathematical Curves and Their Graphical Construction.
4. Practical Engineering Drawing and Third Angle Projection.
5. Shades, Shadows, and Linear Perspective.
6. Descriptive Geometry—Pure and Applied, with a chapter on "Higher Plane Curves and the Helix."
7. Theoretical and Practical Graphics.
8. The Perspective of Reflections.

He later published "Paraphrased Proverbs," in 1933, and "Graphics and Faith," in 1936.

Professor Willson was married to Miss Mary Hewes Bruere in May, 1884. She died nine years later, and in July, 1895, he was married to Miss A. Russell Albertson. The second Mrs. Willson died in February, 1929.

His survivors include three daughters, M. Louise Willson, Elizabeth Willson (Mrs. Warren Buffum), and Edith Willson (Mrs. Harold F. Pellegrin); one son, Albert N. Willson; and eight grandchildren, Barbara, John, Donald, Paul, and Fred Willson, and Francis, Fred, and Edith Pellegrin.

Professor Willson was an active member of many professional societies and made a particular point of attending every meeting possible. He was a fellow of the American Association for the Advancement of Science, and a member of the American Society of Mechanical Engineers, the American Mathematical Society, Phi Beta Kappa (Princeton), and Sigma Xi (Rensselaer).

His remarkable memory for names and faces endeared him to his professional associates and to his students. He could give on sight the name and class of a former student he had not seen for twenty years or more. He was keenly interested in the development and career of all of them. Earl Anderson, the originator of the "cage" masts which were used for many years to support the fire-control tops of United States warships, was one of Professor Willson's students and his design for the mast had its inspiration in one of the models that Professor Willson had used in class. This occurrence pleased and gratified Professor Willson almost more than some of his own achievements.

Professor Willson was known for his inexhaustible interest in his subject and in his profession as an engineer. He holds the unique record of having crossed the Brooklyn Bridge catwalk in 1878, and the George Washington catwalk in 1929, and finally, on his eightieth birthday in 1935, he stood on the catwalk at the top of one of the towers of the Golden Gate Bridge.

He had a deep and lasting interest in his religion and served as Elder in the First Presbyterian Church of Princeton for fifty-three years, 1886–1939.

He was always characterized by his youthful enthusiasm, by the energy he displayed up to the very end of his life, by the scholarly approach he exhibited toward any problem, and by the comprehensive grasp of his subject; but, despite the contributions he made to the graphical sciences and to the art of teaching, he will be long remembered not for his writings nor for his professional achievements but because of the loyalty and admiration he inspired in the hearts of those who had the good fortune to know him as no others could—his students.

Professor Willson was elected a Junior of the American Society of Civil Engineers on September 5, 1883; an Affiliate on October 4, 1892; and a Member on March 15, 1926.

FRANK EDWARD WINSOR, M. Am. Soc. C. E.[1]

DIED JANUARY 30, 1939

Frank Edward Winsor died at the very height of a distinguished career as an engineer and public servant. He will be remembered not more for his professional achievements than for his important public services, his wide sympathetic interests, his friendly spirit of cooperation, and the high integrity of his character. The success which he achieved in his chosen profession may well be attributed in part to his ancestry. His father was George Henry Winsor, a mechanical engineer. His mother was Lucy Jane Draper, whose father, Alpha Angell Draper, was highway commissioner for fifteen years in the town of Lincoln, R. I. His great-great-grandfather, Israel Angell, was a Colonel in the Revolutionary War and a descendant in the fifth generation of Thomas Angell, who came to Providence, R. I., with Roger Williams.

Mr. Winsor was born on November 16, 1870, in Johnston, R. I., later a part of Providence. He attended Brown University, in that city, from which he was graduated in 1891 with the degree of Bachelor of Philosophy., subsequently receiving the degrees of Civil Engineer in 1892, Master of Arts in 1896, and the honorary degree of Doctor of Science in 1929 from that institution. He was the eldest of four brothers, the surviving three being George A., M. Am. Soc. C. E., William H., and Harry D., Assoc. M. Am. Soc. C. E.

Except for miscellaneous work in surveying parties, prior to graduation, Mr. Winsor began his engineering career in August, 1891, with the Metropolitan Sewerage Commission of Massachusetts, successively as transitman and assistant engineer, mainly on preliminary surveys covering a considerable part of the Northern Metropolitan System, and on the construction of the Shirley Gut Siphon and the Deer Island Pumping Station.

From February to September, 1895, he was employed by the late Samuel M. Gray,[2] M. Am. Soc. C. E., a consulting engineer of Providence, first in designing, and later as resident engineer in constructing a sewerage system for Natick, Mass., which cost, when completed, about $200,000. Association with Mr. Gray was to "bear fruit" later. However, he did not finish the sewer job, but left in October to join the staff of the Metropolitan Water Board of Massachusetts. For about five years he worked as an assistant in the Wachusett Dam and Reservoir and the Wachusett Aqueduct Departments. Then he was promoted to assistant engineer in charge of the Weston Aqueduct Department office in Saxonville (Mass.) for two and one-half years, and division engineer in charge of the construction of Division No. 2 of the Weston Aqueduct in Framingham and Wayland, Mass. This included about 2½ miles of masonry aqueduct and about one mile of 90-in. steel-pipe siphon across Happy Hollow, and cost about $500,000.

---

[1] Memoir prepared by a committee consisting of Karl R. Kennison, M. Am. Soc. C. E., Chairman, and William W. Peabody, M. Am. Soc. C. E., and Harry D. Winsor, Assoc. M. Am. Soc. C. E.

[2] For Memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1679.

In February, 1903, he took a position with the Commission on Additional Water Supply for New York City. He was principal assistant engineer in charge of field investigations in the Aqueduct Department. His work covered more than 100 miles of aqueduct line and about 30,000 acres of reservoir sites. He remained with this Commission less than a year, and in November was called back to Massachusetts by the Charles River Basin Commission, successively as division engineer in charge of the design of dam, locks, flood-control structures, etc., and as principal assistant engineer. Apparently his nine months' work in New York was appreciated because in April, 1906, the New York Board of Water Supply called him back, first as senior division engineer for nearly four years and then for five and one-half years as department engineer in charge of the Southern Aqueduct Department. This included construction of about 31 miles of the Catskill Aqueduct and the Kensico and Hill View reservoirs. The aqueduct includes about 13 miles of tunnel varying in size from 14-ft circular pressure tunnel to 17 ft 6 in. by 13 ft 4 in. horeshoe section grade tunnel, and shafts up to a maximum depth of about 560 ft. The cut and cover sections of the aqueduct were generally of horseshoe section equivalent to 17 ft in diameter. The Kensico Reservoir with a capacity of about 33 billion gallons required a masonry dam about 300 ft high with nearly one million cubic yards of masonry (at the time one of the largest masonry dams in the world), an earth dam, and other appurtenances. The Hill View equalizing reservoir at the New York city line has a capacity of nearly one billion gallons. Expenditures for the department were about $35,000,000 which included about $26,500,000 for construction.

Mr. Winsor never lost touch with the work of the New York Board of Water Supply, and for several years before his death he acted as one of its consulting engineers.

In August, 1915, the newly organized Water Supply Board of the City of Providence had just accepted a report from Mr. Winsor's former employer, Samuel M. Gray, recommending a new water supply, and it called Mr. Winsor to Providence as its chief engineer. The work included the construction of a storage reservoir with a capacity of 37 billion gallons which required an earth dam with a maximum height of 100 ft above the ground and 180 ft above the rock; also 26½ miles of substitute highways, and the establishment of the new cemetery. It also included about 14 miles of aqueduct and pipe lines, a small tunnel about 3½ miles long, a purification plant of 50 mgd capacity of the rapid filter type, and two covered distributing reservoirs. The new supply involved an expenditure of about $21,000,000.

As the work in Providence was nearing completion, the Metropolitan District Water Supply Commission, which had just been named by the Governor of Massachusetts to construct major additions to the water supply sources of the Metropolitan Water District, was looking for a chief engineer. Mr. Winsor's broad experience in this field of work and familiarity with the local conditions made him the logical candidate. He began the work in October, 1926. It consists of an extension westerly to the Ware and Swift rivers from Wachusett Reservoir which he, as a young man, had helped to build. The new Quabbin Reservoir in the Swift River valley will have a capacity of 415 billion gallons, will flood an area of about 39 sq miles, will be 18 miles long, and will have a maximum depth of 150 ft with a shore line of more than 175 miles. The area is so great that it has necessitated relocating the boundaries of six towns and three counties, and wiping four towns out of corporate existence. It also required 36 miles of relocated state highways to replace existing highways in the reservoir area. The variety of the activities in which Mr. Winsor and his organization engaged can be appreciated from the fact that a new cemetery was required in which about 7,500 bodies buried in the area affected by the reservoir required reinterment. About 80,000 acres of land were acquired for sanitary protection and construction purposes in the reservoir area.

The gravity connection to Wachusett Reservoir is by a 24.6-mile tunnel which was practically completed in 1934. This tunnel passes directly beneath the Ware River Intake Works, completed in 1931, by means of which flood flows from the Ware River are dropped into the tunnel and can be diverted in either direction—easterly to Wachusett Reservoir or westerly to Quabbin Reservoir. Two earth dams will impound the waters of Quabbin Reservoir. The smaller dam, called Quabbin Dike, is 2,140 ft long, 135 ft high above the bed of Beaver Brook, and 264 ft above the surface of sound ledge. Mr. Winsor completed it in 1937. The larger main dam is 2,640 ft long, 170 ft high above the bed of Swift River, and 295 ft above sound ledge, and will contain about 4 million cubic yards above the original surface. This dam was nearly completed at the time of Mr. Winsor's death, and the Water Supply Commission very fittingly named it "Winsor Dam" in his memory. Each of these dams was constructed by the hydraulic-fill method, above a deep concrete cutoff wall built by sinking a row of caissons across the valley.

A number of articles in Society publications have covered various aspects of this work. These include a group of four papers, one by Mr. Winsor, in the December, 1929, *Proceedings*; a symposium on Surface and Subsurface Investigations in the 1937 *Transactions*, to which Mr. Winsor contributed a foreword; a general description of the project which he wrote for the June, 1934, *Civil Engineering*; a paper on the Ware River Intake Works by Karl R. Kennison, M. Am. Soc. C. E. (who succeeded Mr. Winsor as chief engineer) in the August, 1934, *Civil Engineering*; a paper on the Quabbin Dike by Stanley M. Dore, M. Am. Soc. C. E., in the 1938 *Transactions*; and a paper on surveys for the Swift River Reservoir by N. LeRoy Hammond, M. Am. Soc. C. E., in the February, 1931, *Proceedings*.

Mr. Winsor's work with the Water Supply Commission involved much more than the Ware-Swift project. In 1927 he developed the Southern Sudbury system of the District as an emergency supply by constructing 7 miles of pipe lines connecting the purer upland sources with the Northern Sudbury system. The Ware-Swift construction had hardly begun, with contracts for shaft sinking, before the State of Connecticut in January, 1928, filed a bill in equity in the United States Supreme Judicial Court against the Commonwealth of Massachusetts objecting to the diversions from the Ware and Swift rivers. Mr. Winsor's energies were thereafter largely devoted to the collection and presentation of data for this important suit. The decree of the court, rendered three years later, dismissed Connecticut's bill of complaint and upheld Massachusetts' right to make the diversions. The successful outcome of this important case was due in no small measure to Mr. Winsor's marshalling and correlation of the facts.

About two and one-half years before his death, Mr. Winsor was asked to investigate methods to improve the distribution of water from the sources of supply of the Metropolitan Water District, and more adequately to prevent the pollution due to the fact that all the water from Quabbin and Wachusett reservoirs must pass through the old Sudbury system and the grade line aqueducts. As a result of his thorough investigations, the legislature gave the Commission the additional task of constructing a pressure aqueduct to by-pass the Sudbury system and deliver the water directly from Wachusett Reservoir to the District, at a sufficiently increased pressure to eliminate much of the present pumping in the District.

Due in no small part to the efficient organization and conduct of the work on the Ware-Swift extension, Mr. Winsor had reported an estimated saving of approximately \$12,000,000 on the original appropriation of \$65,000,000 which was made for the Ware-Swift extension, and in August, 1938, following Mr. Winsor's pressure aqueduct report, the Commission was allowed to spend this sum, supplemented by a federal grant, to take the necessary first steps in the aqueduct construction. Mr. Winsor proceeded to organize the work, and contracts totaling about \$9,000,000 had been awarded, and some of them well underway, at the time of his death.

The District owes a great deal to him personally for the efficient planning and conduct of the work. His contacts with his engineering associates, contractors, and public officials were marked by tactful understanding and fair dealing, which won for him a host of friends. Indicative of the high regard of his associates and the acclaim with which his appointment to the position of chief engineer of the Metropolitan District Water Supply Commission was received, is the complimentary dinner given to him by the entire Affiliated Technical Societies of Boston in January, 1927.

In all the traits that make for a successful engineer and a worth-while man, Frank Winsor was outstanding. His mind could grasp the theoretical as well as the practical details, yet he never lost sight of the larger aspects. He could deal equally well with a lowly subordinate, an important contractor, or an official commissioner. His presence engendered confidence, which grew and grew with acquaintance.

He worked hard, perhaps too hard. Long hours were no novelty to him when he became engrossed in a problem. But he knew equally well how to play and when the occasion suited, he would enter into any hilarity that was afoot with the zest of a boy. The merry twinkle of his eye and the contagious chuckle were characteristic. Thus he was a popular figure at Society gatherings, alumni meetings, or dinners of engineers. He was most punctilious in keeping such engagements, as well as with his more serious duties.

In his home life, be it in the city or at the shore, he was at his best. He and Mrs. Winsor loved company and were marvelous hosts. The social events they sponsored for members and families of his engineering organization were noted.

Not an orator, he was an easy speaker in public. He impressed particularly with his marshalling of facts, his logic, and his great memory for details. Around the conference table this quality was especially effective.

It is not strange, therefore, that his services were in demand on committees dealing with professional matters. He was most generous of his time, as well as his means, in serving engineering, educational, and charitable organizations. Speaking only of his Society activities and mentioning but a few of his services, his appointments included the Executive Committee of the Board of Direction (two years), Committee on Honorary Membership (two years), on National Hydraulic Laboratory, on Federal Reorganization, on Hydraulic Fellowships, on J. Waldo Smith Fund, Society representative on Engineers' Council for Professional Development, Trustee of United Engineering Society.

Following Mr. Winsor's death, the Metropolitan District Water Supply Commission inscribed on its records a memorial which recited his professional achievements and concluded:

> "The forty-seven years of service given to the public by Mr. Winsor and the extensive works constructed under his supervision are a lasting memorial to his vision and industry. To his friends and associates his unlimited kindness and patience, his fidelity to all tasks entrusted to him, and above all his faithfulness to what he conceived to be right constitute his true imperishable memorial."

Mr. Winsor was married to Catharine Holbrook Burton in Providence on October 25, 1893. They had three children: Lucy Burton (Mrs. Hugh B. Killough), associate professor of economics at Wellesley College, Wellesley, Mass.; Edward, a practising lawyer in Providence; and Catharine (Mrs. Hazen H. Ayer) of Winchester, Mass.

Mr. Winsor was a member of the American Water Works Association, president of the Providence Engineering Society in 1922–1923, president of the New England Water Works Association in 1927 and an honorary member at the time of his death, and president of the Boston Society of Civil Engineers in 1929. He also served a term as a director of the Municipal Engineers of the City of New York. He was a Fellow of the American Academy of Arts and Sciences, a Thirty-Second Degree Mason, and a member of Sigma Chi fraternity, Sigma Xi, and the Boston City Club. He was president of the Brown Club of Boston in 1931, a Trustee of Brown University, and an honorary member of the Brown Engineering Association.

Mr. Winsor was elected an Associate Member of the American Society of Civil Engineers on November 4, 1903, and a Member on December 5, 1905. He served as a Director of the Society in 1922–1924, and Vice-President in 1930–1931.

CHARLES NICHOLSON WRIGHT, M. Am. Soc. C. E.[1]

Died September 6, 1939

Charles Nicholson Wright, the second son of the late Edward Thomas Wright, M. Am. Soc. C. E., and Lucy (Nicholson) Wright, was born at Fifth Street and Fort Street (later Broadway), Los Angeles, Calif., on November 29, 1876, his family having moved to Los Angeles from Cobden, Ill., the previous year.

In July, 1875, his father established an engineering office on the site of the present Los Angeles post office and became one of the leaders in the development of Los Angeles and vicinity. He was elected county surveyor in 1880, and afterward was elected twice more to the same office, the last term being 1895–1898, during which period he developed the first complete map of Los Angeles County. During their spare time and vacations, Charles Wright and his brother, G. A. Wright, were tutored by their father in engineering practices, so that it was natural for them to follow in their father's footsteps when they grew up.

After graduating from primary and high schools in Los Angeles, Charles Wright went to the University of California, at Berkeley, and graduated in 1902 with the degree of Bachelor of Science in Mining Engineering. For the next five years he was employed by the Arizona Copper Company and the Lower California Copper Company in the development of their mines in Arizona and Lower California. He then went to Goldfield, Nev., where he was engaged in mining work and the construction of the Las Vegas and Tonopah Railroad.

In the fall of 1909, Mr. Wright was employed as tunnel superintendent on the construction of the Los Angeles aqueduct. From January, 1910, to August, 1911, and from October, 1913, to November, 1917, he was engaged in county highway work in Los Angeles, Riverside, and Ventura counties. This position included design and construction work of the various highway systems. From September, 1911, to September, 1913, he was engaged in the development of lead-silver property in Inyo County, California. From the fall of 1917 until the summer of 1922 he was with the Shell Oil Company, Inc., in Los Angeles, engaged in general engineering work.

---

[1] Memoir prepared by Charles R. Sumner, M. Am. Soc. C. E.

In the summer of 1922 Mr. Wright joined his brother who, since the death of their father in March, 1917, had been continuing the business under the name of The Wright Engineering Company. On the death of his brother, Charles Wright took full charge of The Wright Engineering Company and continued the business until his death. Mr. Wright was also city engineer for the City of San Gabriel, Calif., from May, 1923, until his death, except for the period from May, 1935, to May, 1938.

Mr. Wright was married to Mary Jane Allen of San Francisco on June 2, 1922, and soon after their marriage they moved to their home in San Gabriel. His widow survives him.

Mr. Wright was very accurate and precise in his work, and was an exceptionally good designer and draftsman. He had an even disposition, but was supersensitive of criticism if he thought he was being misjudged. Although somewhat retiring by nature, he was most friendly and helpful to his fellow men. His friends will miss his bubbling laugh and friendly smile, which endeared him to every one with whom he came in contact.

Mr. Wright was elected a Member of the American Society of Civil Engineers on June 9, 1930.

JOHN MORTON BILLING, Assoc. M. Am. Soc. C. E.[1]

DIED JANUARY 9, 1939

John Morton Billing was born on February 1, 1903, in Blackpool, England. He was educated at Bentham Grammar School and at London University, both in England. At the University he received the degree of Bachelor of Science, *cum laude,* in 1922, and later was elected an Associate Member of the Institution of Civil Engineers and also of the Institution of Municipal and County Engineers.

From January to May, 1924, he was lecturer at the Southend Evening Technical School. In June, 1924, he was appointed junior assistant in the County Borough Engineer's Office, Corporation of Southend-on-Sea, England, in Building Inspectors' and Town Planning Sections. In February, 1926, he was appointed assistant in the Borough Engineer's Office in Crewe, England, and worked on surveys, etc.

In September, 1926, he was appointed an assistant engineer in the Malayan Public Works Service, and he remained in the Public Works Department (PWD) until he died at the age of thirty-six.

As assistant engineer, he was stationed in many different parts of Malaya. He was engaged in the sanitation branch in Singapore, on a water supply project in the Province of Wellesley, and on the construction of an aerodrome in the State of Perak. In addition to these posts he acted as assistant engineer in PWD districts in the States of Johore, Perak, and Pahang. In

---

[1] Memoir prepared by A. Wear, Personal Asst. to Director of Public Works, Straits Settlements, Singapore, Straits Settlements.

1935 Mr. Billing was promoted to the rank of executive engineer and, after being in charge of Kuala Lipis district, Pahang, was transferred in 1935 to Segamat in Johore, where he remained in charge until his death.

The work of an engineer in charge of a PWD district does not lend itself easily to brief description of specific works. Road maintenance, the construction of new roads, and the erection of public buildings form part of his normal duties. In addition, he is responsible for water supplies, anti-malarial drainage, and all branches of government engineering work or construction in his district.

Apart from his normal duties, Mr. Billing was an active supporter of the Malayan Association of the Institution of Civil Engineers and of the Engineering Association of Malaya, a society devoted to the more general aspects of engineering. In the *Proceedings* of both of these bodies, many original papers by Mr. Billing have been published, including " Progressive Development of Roads " and " An Approach to the Problem of Improvement of Roads." Mr. Billing did not confine his interests to the practice and theory of engineering, but was keenly interested in science generally. He devoted a considerable portion of his spare time to the study of astronomy.

Mr. Billing was elected an Associate Member of the American Society of Civil Engineers on August 15, 1932.

JOSEPH PATRICK BURNS, Assoc. M. Am. Soc. C. E.[1]

DIED JULY 4, 1939

Joseph Patrick Burns, well-known civil engineer and treasurer of Burns Brothers and Haley, Inc., General Contractors, and only surviving member of the Burns Engineering Company, Consulting Engineers, died at his home at Watertown, N. Y., on July 4, 1939, after a long illness.

Mr. Burns was born at Watertown on March 20, 1875, a son of Patrick and Mary (Kinny) Burns. He was the last surviving member of a family of fourteen children. His father, Patrick Burns, came to Watertown in 1847 from County Sligo in Ireland, and became a prominent contractor.

Mr. Burns received his education in the Public and Parochial Schools of Watertown and was a member of the Class of 1893 but did not graduate on account of illness. He finished his preparatory school work at the Stiles Preparatory School of Ithaca, N. Y., and was graduated in 1894.

For a time he was engaged in construction work and from May, 1894, to June, 1896, he was engaged as architectural draftsman with the late John W. Griffen, Architect of Watertown. From that time until he entered Cornell University at Ithaca he served as a member of the New York City Mounted Police, under the late President Theodore Roosevelt, then New York City Commissioner of Police.

---

[1] Memoir prepared by William T. Field, M. Am. Soc. C. E.

In 1898 he entered Cornell University, taking up Chemical Engineering for one year. Later he transferred to the University of Wisconsin, at Madison, Wis., graduating in 1904 with the degree of Bachelor of Science in Civil Engineering. After graduation he took special work in German and other languages.

During the summer of 1901 he worked as Structural Draftsman in New York City. From June, 1902, to January, 1903, he held the same position with the Louisville and Nashville Railroad Company. In the Summer of 1903 he was engaged in surveying and making property maps for Dane County, Wisconsin.

From May, 1904, to March, 1905, Mr. Burns was bridge draftsman on drawings and computations for canal-lock machinery and bridges in the Department of the New York State Engineer; from March to December, 1905, he was civil engineer and superintendent of construction with the Chief Quartermaster, United States Army, Department of Texas at San Antonio, in responsible charge of designing, estimating, and supervising construction of sewer and water-works systems, buildings, etc. From December, 1905, to July, 1906, he was with the Department of the New York State Engineer, serving as bridge draftsman until February, 1906, then as Assistant Engineer making drawings and computations for locks, dams, retaining walls, etc., in connection with the Barge Canal construction.

Mr. Burns was a member of the firm of Burns Brothers and Haley, Inc., from July, 1906, to November, 1907, constructing New York State roads and investigating and making designs for the improvement of water power along the Black River in New York.

In November he returned to Albany, N. Y., to accept a position as Assistant Engineer on the Barge Canal, and when the Highway Department was created, he was transferred to that department and assigned to the Watertown office.

In April, 1911, he was appointed Deputy Division Engineer under Guy H. Miller, then Division Engineer in the Watertown office, and was in charge of the supervision of construction in St. Lawrence and Franklin counties and the northern part of Jefferson County. He later left the Highway Department to devote his attention to the contracting and engineering business controlled by the Burns Brothers. This firm attained a wide reputation, having constructed numerous power plants, dams, paper mills, and other industrial plants, and churches and schools throughout northern New York, as well as important business buildings.

One of the most ardent advocates of the St. Lawrence Seaway and hydroelectric development, Mr. Burns had delivered many addresses on the subject and had worked in conjunction with the late Delos M. Cosgrove, Vice-Chairman of the Power Authority of the State of New York.

Mr. Burns was a trustee of the Watertown Savings Bank; a member of the Holy Family Church; Watertown Council No. 259, and Watertown Assembly, Fourth Degree, Knights of Columbus. He was an industrious and hard working man, but above all, kindly and lovable, true to his friends, and just to all.

In 1907 he was married to Mary T. Carr, of Madison, Wis., who died on April 26, 1917. A daughter, Mrs. Elizabeth M. (Charles W.) Sloat, survives. On June 30, 1919, Mr. Burns was married to Mary F. Valin of Watertown who, with Robert Celestin Burns, Katherine Anne Burns, and Mary and Joseph Burns, twins, as well as Mrs. Sloat, two grandchildren and several nephews, survives him.

Mr. Burns was elected an Associate Member of the American Society of Civil Engineers on December 1, 1908.

CHARLES PAGE COMEGYS, Assoc. M. Am. Soc. C. E.[1]

DIED JUNE 5, 1939

Charles Page Comegys was born on February 12, 1898, at Easton, Talbot County, Md., the son of Charles Edward and Minna Whitman (Pretzman) Comegys. The Comegys emigrated from Holland to Maryland during the early days of this Republic. Page, as he was known to all his friends, attended the public schools of Easton and Baltimore, Md., and was graduated from the Baltimore Polytechnic Institute, at Baltimore, in June, 1918.

Just prior to his senior year, Mr. Comegys spent one summer—June to October, 1917—as inspector for the Maryland State Roads Commission and, upon completion of his school work, in June, 1918, he reported to Camp Meade (later Fort George G. Meade), Maryland, for service with the 304th Field Service Battalion, and embarked for France with his battalion in July, 1918. His tour of duty with the American Expeditionary Forces lasted one year.

Returning to his native state and the Roads Commission, Mr. Comegys was made inspector on various road and bridge enterprises, until May, 1921, when he was promoted to general inspector, reporting directly to the district engineer. In October, 1924, he resigned from the roads body to accept a position as field and office engineer for Herbert G. Campion, building contractor, of Philadelphia, Pa., on extensive residential and church construction. Here he received training in the building field which was later to prove invaluable to him.

In April, 1928, Mr. Comegys formed a partnership with Arthur Farmer, with offices in Easton, and engaged in general construction on highways, bridges, buildings, and wharves, until 1932, when Mr. Farmer withdrew from the firm. The business was then conducted until Mr. Comegys' death under the name of Charles Page Comegys. During this period he built many beautiful waterfront summer homes in Talbot County for wealthy Pittsburgh and New York families.

On September 18, 1931, Mr. Comegys was married to Mabel Helen Resley, of Hancock, Md., who, with his mother and a sister, survives him. They had no children. His widow has continued his contracting business under the name of Charles Page Comegys Company, Incorporated.

---

[1] Memoir prepared by John K. Flick, M. Am. Soc. C. E.

Mr. Comegys was a member of the Society of American Military Engineers, the American Legion, Masonic Fraternity, and was a Thirty-Second Degree Scottish Rite Mason. His clubs were: Chesapeake Bay Yacht Club, Talbot Country Club, Miles River Yacht Club, and the Tred Avon Yacht Club. He was extremely fond of water sports and most of his week-ends would find him on one or another of the beautiful bodies of water for which Talbot County is noted. He also owned a summer home on an arm of the Tred Avon River.

Mr. Comegys had the faculty of making friends and holding them. His broad smile and warm handshake are remembered by all who met him. His home was his friends' home as well, and his hospitality will never be forgotten. His passing is mourned by all who had any contacts with him in life. He was buried in the graveyard of Old St. Paul's Episcopal Church, near Chestertown, Kent County, Md., one of the oldest houses of worship in the state, antedating the Revolutionary War.

Mr. Comegys was elected a Junior of the American Society of Civil Engineers on January 14, 1924, and an Associate Member on February 10, 1930.

FREDERICK WEBSTER DECK, Assoc. M. Am. Soc. C. E.[1]

DIED SEPTEMBER 26, 1938

Frederick Webster Deck was born in Washington, D. C., on March 28, 1896, the son of William Meade Deck and Annie (Hendricks) Deck. The Deck family, originally from Saxony, Germany, settled in Pennsylvania, and in 1810 migrated to West Virginia (then Virginia). They made their home in the vicinity of Harpers Ferry, a name which was to reverberate throughout the nation two generations later. The Hendricks family originally came from Holland.

Mr. Deck received his education in Washington, D. C., attending the Towers grade school, Eastern High School, and George Washington University. He commenced his studies in grade school in the fourth grade, having received his preliminary training at home from his father. While in high school, he was rewarded with the position most highly desired by his fellow students—the captaincy of the school cadet company. The attainment of this honored post, awarded to him for his outstanding scholastic endeavors, his unmistakable leadership, and his general popularity, indicates clearly to those who knew him later that even in his youth he evinced those attributes which in his maturity brought him a large measure of respect and devotion from all his associates. In 1914 Mr. Deck entered George Washington University, but left in 1917, in his senior year, to enter the U. S. Army.

---

[1] Memoir prepared by J. E. Havelin, Assoc. M. Am. Soc. C. E.

Appointed as a Second Lieutenant of infantry in the regular army in October, 1917, he was under instruction at the army service schools, served with the 48th and 63d Infantry in various camps in the South, and served in France until December, 1919. He was transferred in July, 1920, to the Corps of Engineers, as a First Lieutenant. Shortly afterward he became Captain, and served with the 1st Engineers, a unit in the Army of Occupation at Coblenz, Germany, until March, 1922. It was while in service at Coblenz that Captain Deck was thrown from a horse in a riding hall, seriously injuring his spine and necessitating his retirement from the army. This was a catastrophic blow to him but borne stoically as were the long years of hospitalization and his constant suffering. He was retired from active service with the rank of Captain in the Corps of Engineers in December, 1922.

It was at this point of his career that Captain Deck showed his mettle. His was the example to be pointed to with pride—that somewhat rare achievement of man surmounting excruciating agonies of the flesh through indomitable will power and the determination of mind not to succumb to bodily ills. Perhaps, also, here was another instance of Nature's effort to rectify damage through compensation, such as one sees in the heightened sense of hearing in those bereft of the sense of sight. It acted in his case in rendering more acute an already brilliant mind. In proportion as his bodily activity was restricted by months of lying in hospitals for treatment and convalescence, his mind moved at a feverish pace. He showed his avid thirst for knowledge by the wide range of subjects he studied—philosophy, economics, languages, and all phases of engineering. He picked up his collegiate studies where they had been interrupted in 1917, and in 1924 received the degree of Bachelor of Arts from George Washington University, to be followed in 1925 with the degree of Bachelor of Science in Civil Engineering from the University of Colorado, in Boulder, Colo. He supplemented these studies with miscellaneous courses taken in the University of California Extension School. Later in 1929, after being active in the engineering profession for some time, he received a postgraduate degree of Civil Engineer from the University of Colorado. So keen was his desire for study that in 1936 and 1937 he attended evening classes in the Graduate School at the University of Pennsylvania, in Philadelphia, Pa., with the purpose of obtaining a Doctor's degree in Mathematics. Unfortunately, due to failing health, he was unable to complete these studies.

In August, 1925, having responded to numerous operations and various treatments for his injured spine, but compelled to wear a steel brace, Captain Deck entered active professional work as a designing and supervising engineer in the Steel Tower Section of the Philadelphia Electric Company. His duties in this position called for skill of a high order, not only in ability to plan and direct specialized engineering projects, but also in the handling of delicate negotiations with other corporations for the purpose of coordinating the design of structures for joint use. He never spared himself, although physically handicapped, in his determined effort to carry a project through to a successful conclusion. His associates have had occasion, while accompanying him on many reconnaissance expeditions over exceedingly rough terrain and under a scorching sun, to marvel at the spirit of this unusual man who could continue at an exhausting pace, despite the pain he was obviously suffering.

Captain Deck was responsible in a large measure for the ingenious designs of the supporting structures and their foundations involved in the successful ventures in unusual transmission line construction, known as the Reading Overbuild Lines. These are two 66-kv transmission lines, following the east and west banks of the Schuylkill River, in Pennsylvania, and constructed on steel towers built over the tracks of the Reading Railroad. Approximately forty structures are used on each overbuild section, and because the limitations of the right of way required adaptation of the structures to the ground, rather than the usual practice of standardization of structures, some six individual types of structures were required on each overbuild section. Captain Deck deserves a high place in the ranks of successful engineers when one considers the part he played in solving the complexities of a problem in which the interests of two utilities had to be safeguarded by providing structures of maximum safety erected within the narrow confines of busy railroad rights of way. Attention should also be drawn to his skill in coordinating the manifold phases of the construction involved, not only with normal, heavy railroad traffic but with the concurrent railroad company's construction project. Captain Deck has described the two overbuild transmission lines very ably in several articles.[2, 3, 4]

In 1929, when the Engineering Department of the Philadelphia Electric Company was reorganized, Captain Deck became a senior engineer in the Mechanical Engineering Division, in which position he was in full charge of all civil and structural engineering work. In this position his ever-present originality of mind had full play. It was a cardinal point with him never to accept the standardized methods of attack—the engineering clichés, so common in the profession. He was intrigued by the use of new angles of attack on problems of an empirical nature, but he was fully in his element in solving the unusual, the complex, and the difficult type of problem.

Those familiar with the specialized engineering involved in electric-utility operation will readily appreciate that opportunities for a fecund and aggressive mind are ever present in the transmission-line field, and especially in the structural phases of power-plant design. Captain Deck was given "carte blanche" when, in the course of the reconstruction of one of the company's generating plants, he recommended the use of a new type of suspension coal bunker. That he proceeded with this design on the basis of original formulas, and that its complete success has elicited from the operating engineers the statement that this bunker is vastly superior to any other in the Philadelphia Electric Company's system, is a tribute of a high order to his engineering skill, as well as to his superiors who had unfailing confidence in his genius. Inci-

[4] *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 944.

dentally, Captain Deck left unfinished a paper on the design of this suspension bunker. His intention was to present his theories to those interested so that full discussion of its relative merits might ensue and similar bunkers be erected profitably by others in the industry.

In the transmission-line field, also, his exceptional talents were early recognized, and assignments to national society committees engaged in this field of work followed in quick succession. He was a member of the Power Transmission and Distribution Committee of the American Institute of Electrical Engineers (A. I. E. E.) for many years, and served for several years as chairman of its Subcommittee on Conductors, Towers and Wood Poles. He was chosen as the A. I. E. E. representative on the committee currently working on the revision of the National Electrical Safety Code, serving on two of its subcommittees, one on " Clearances " and the other on " Strength Requirements and Loading." In allied fields, his interest was so keen and his talent so obvious that the company employing him asked him to be its representative in the American Concrete Institute, and also to represent it on Committee A–5 on " Corrosion of Iron and Steel " of the American Society for Testing Materials. All of these responsibilities he handled with his customary thoroughness, and with his unswerving devotion to what he considered to be the best interests of his chosen profession.

Captain Deck was an exceedingly fair man in his dealings with others His was the military manner, the result of army training to receive and execute orders, to obey and be obeyed according to the rank and position eventually reached through one's ability. However, he was not a martinet, and he vehemently scorned blind subserviency and lackey attendance upon superiors. On one occasion his disgust at the actions of an associate was so strong that he penned the following words—words so descriptive of his sense of proportion or perspective in dealing with others that they may well be summed up as typical of his attitude on that subject:

> " A man who constantly trembles for fear of ' what his superior will say ' or ' what people will think ' soon loses self respect, initiative, and individual worth. Respect for the opinion of others, their knowledge, their rank, is conducive to profitable self-discipline. Subservience leads to a contemptible existence. * * * Diplomacy, tact, and understanding patience have their place. Force, firmness, and an unyielding mien have theirs, but brow-beating, taking unfair advantage, and cowardly overbearing have not a place in the repertoire of the successful man."

Captain Deck was married to Mary Evelyn Jolls on February 3, 1921, shortly before he sailed for duty with the Army of Occupation in Germany. Mrs. Deck's forbears were very active politically in Delaware.

Captain Deck is survived by his widow and three sons, Frederick Webster, Jr., William Meade, and John Wheaton; and also by a brother, William H. Deck.

Captain Deck was elected an Associate Member of the American Society of Civil Engineers on July 16, 1928.

CLYDE HENRY FENTON, Assoc. M. Am. Soc. C. E.[1]

DIED AUGUST 7, 1939

Clyde Henry Fenton was born at Neenah, Wis., on March 6, 1897, the son of Merton O. and Anna (McCallum) Fenton. His preliminary education was obtained in the public schools of Kimberly and Appleton, Wis. He then entered Lawrence College, at Appleton, from which he was graduated in 1918 with the degree of Bachelor of Arts. In 1921 Mr. Fenton entered the Colorado School of Mines at Golden, Colo., and was graduated in 1923 with the degree of Bachelor of Science in Mining Engineering.

After receiving his degree at Lawrence College, he spent three years as instructor of chemistry and physics in the public schools of Escanaba, Mich., and Antigo, Wis. In 1923 he took his first position in the engineering field—that of underground foreman in charge of shift in the Creighton Mine, near Sudbury, Ontario, with the International Nickel Company of Canada, Ltd. He continued in this work until 1930, at which time he went to Houston, Tex., as a member of the firm of the Blue Bonnet Tile Company, which was engaged in contracting and general supervision of the installation of tile.

In 1934 Mr. Fenton left the Blue Bonnet Tile Company to become computer-draftsman on a four-county aerial photo-mapping project with the U. S. Geological Survey in the Houston office. When this work was completed, he was employed by the U. S. Forest Service in Lufkin, Tex., as photogrammetrist in connection with the photo-mapping project for land acquisition for the Sam Houston National Forest in the vicinity of that city. While with the same organization he later became senior engineering draftsman. When the Brazos River Conservation and Reclamation District established an engineering and mapping organization in 1935, he left the U. S. Forest Service to join that organization as photogrammetrist on the photo-mapping of thirteen major reservoir areas along the Brazos River and its tributaries. In July, 1937, he was made office engineer in the headquarters office at Temple, Tex. While working in this capacity he did a considerable amount of independent research in connection with the Multiplex Aero-Projector which was being used for the making of topographic maps by his organization. In November, 1938, he took up duties with the Brazos River Conservation and Reclamation District, assisting in the design of earth-fill dams for water conservation purposes in western Texas.

Mr. Fenton passed away on August 7, 1939, at his home in Temple, death being caused by a sudden heart attack. He had been in good health, and his death was most unexpected and a great shock to his many friends.

He was a member of the American Society of Photogrammetry, being Treasurer of the Texas Section. He was also a member of the First Presbyterian Church.

---

[1] Memoir prepared by L. M. Baugh, Assoc. M. Am. Soc. C. E.

He was married to Louise M. Brusse in Holland, Mich., on June 25, 1924. He is survived by his widow; a daughter, Marjorie Jean; and a son, Robert M. His mother and one sister, Dorothy M. Fenton, also survive him.

Mr. Fenton was elected an Associate Member of the American Society of Civil Engineers on May 17, 1937.

GEORGE FARNSWORTH FISK, Assoc. M. Am. Soc. C. E.[1]

Died September 4, 1939

George Farnsworth Fisk was born on September 27, 1878, in Hyde Park, Mass., the son of George Washington Fisk and Eloise Mary (Farnsworth) Fisk. He received his early education in the public schools of Boston, and entered Massachusetts Institute of Technology, at Boston, Mass., in 1897, and finished his sophomore year in June, 1899.

His first employment in his climb to become a distinguished engineer was as a rodman with the New York, New Haven and Hartford Railroad Company. Later, in 1900, he accepted a position as assistant engineer with the U. S. Government under Col. William S. Black, on triangulation survey of fortification in Cuba. Finishing this work in 1903, he was employed as assistant engineer with the United States Appraisal Company of Boston, in charge of surveys of industrial plants and making appraisals.

During this latter work he was transferred to Buffalo, N. Y., to make a survey and appraisal of the large Schoellkopf, Hartford and Hanna Company's chemical works. He was so favorably impressed with Buffalo that he decided to make it his future home and went to work as a transitman with the Pennsylvania Railroad Company. While with this Company he laid out the new railroad shops at Olean, N. Y., and was on the construction of the Goodyear Ship Canal at South Buffalo and the double-span, plate-girder bridge at Hawthorn, Pa.

In May, 1905, Mr. Fisk entered the employ of the City of Buffalo, in the Bureau of Engineering, as a draftsman. During his four years as draftsman, he was assigned to survey and triangulation work. He also appraised all the railroad crossings and bridges in the City of Buffalo. In 1909, he was appointed chief draftsman and took over the investigation of the stability of bridges and viaducts under various loadings.

In 1914 he was appointed assistant engineer in the Bureau of Engineering and was immediately placed in full charge of street paving. During his fourteen years as assistant engineer, Mr. Fisk made many changes in the manner of laying pavements, substituting brick and asphalt for cobblestone and macadam. He established a Paving Laboratory and reorganized the Inspection Division. Under his direction the paving of streets increased yearly. He was chairman of the Brick Committee of the American Society of Municipal Engineers; chairman of the Brick and Block Pavement Committee of the American Society of Testing Materials; director of the Clay Products Institute of America; chairman of the Committee on Sizes and Styles of Paving Brick, Division of Simplified Practice, Department of Commerce, United States of America; and member of the Permanent International Association of Road Congresses.

---

[1] Memoir prepared by Harry M. Glassmire, M. Am. Soc. C. E.

In 1928 Mr. Fisk was appointed commissioner of public works of the City of Buffalo and served three years. During this time the $7,000,000 city hall, the State Normal School of Buffalo, the Hertel Avenue trunk sewer (costing $1,200,000), and the Buffalo city court building were constructed under his supervision. Many changes in engineering procedure and policy were instituted during his administration.

In 1931 Mr. Fisk entered private practice as a consulting engineer, and was often called in consultation in many cities. In 1936 he accepted a position as construction adviser for the U. S. Housing Authority. In this capacity he built two large housing projects, and was completing the third at the time of his death.

With the death of Mr. Fisk the City of Buffalo and the federal government lost a faithful servant. Unfailing courtesy, dignified cordiality, tolerance, and kindliness were George Farnsworth Fisk's characteristics. He was liberal in his views and noted for his fairness and ethical dealings in his engineering contacts with others.

Among his social activities, Mr. Fisk was past master of the Mystic Art Lodge No. 899, Free and Accepted Masons; past high priest of the Triangle Chapter No. 314 of the Royal Arch Masons; a Scottish Rite Mason and a Noble of the Mystic Shrine; and a member of the Buffalo Chamber of Commerce, Rotary, Elks, and the Orioles clubs. He attended the Richmond Avenue Methodist Episcopal Church.

On August 26, 1906, Mr. Fisk was married to Minnie Florence Torge. He is survived by his widow, one son, George William, and one daughter, Dorothy Eloise.

Mr. Fisk was elected an Associate Member of the American Society of Civil Engineers on January 3, 1911.

FRANCIS JAMES FITZPATRICK, Assoc. M. Am. Soc. C. E.[1]

Died July 16, 1939

Francis James Fitzpatrick was born at Chicago, Ill., on June 28, 1884. He was the son of Francis James Fitzpatrick and Frances (Carrol) Fitzpatrick.

---

[1] Memoir prepared by H. E. Anderson, Esq., Senior Engr., U. S. Engr. Office, Pittsburgh, Pa.

His father was captain of sailing vessels for a long period and for many years was master of his own ship. Upon retirement from this occupation he was appointed fire marshal of the City of Chicago. In 1893, during the World's Fair in Chicago, the Cold Storage Building of the Fair was completely destroyed by fire with great loss of life. Fire Marshal Fitzpatrick, while leading his men in the work of rescue, died heroically and was honored accordingly by the city.

The boy's mother died when he was two years old, whereupon he made his home with an aunt, Mrs. Katherine Leonard, to whom he was deeply devoted. Francis James Fitzpatrick was the only child of Frances (Carrol) Fitzpatrick. However, he had an older half brother, Luke Fitzpatrick. After his wife's death, Captain Fitzpatrick spent as much time as practicable with his young son and they were very close to each other in their affection. The tragic death of his father was a great shock to the small boy of nine. His devotion to and admiration for his father made a deep and lasting impression upon him and he too was to become possessed of the courage, strength of character, and integrity of Captain Fitzpatrick, the sailor and hero. He was graduated from Hyde Park High School and then went to Armour Institute of Technology, in Chicago, majoring in civil engineering.

Francis Fitzpatrick, the young man, early became interested in railroad and construction engineering, an interest which he maintained intensively throughout the remainder of his life. In March, 1905, before he had yet attained his twenty-first birthday, he began his engineering career with the Indiana Harbor Railroad Company, first as rodman and later as instrumentman in charge of a residency. In March, 1906, he became topographer for the Cairo and Tennessee River Railway Company. In May of the same year he became instrumentman in charge of a survey party for a fuel company. The next month he returned to railroad work and held the following positions: June to November, 1906, topographer for the Cananea, Yaqui River and Pacific Railway; December, 1906, to January, 1907, leveler and transitman for the Oregon and Washington Railway Company; February to October, 1907, leveler and transitman for the Chicago, Milwaukee and St. Paul Railway Company; December, 1907, with the B. J. Arnold Company on appraisal of railway property; January, 1908, transitman with the Northwestern Elevated Railway Company, in Chicago; and September, 1908, to July, 1909, draftsman and office engineer for the North Coast Railway Company.

Mr. Fitzpatrick then left railroad work to become assistant to the superintendent of the Columbia Canal Company on maintenance and extension of an irrigation system at Attalis, Wash., but again took up railroad work in October, 1909, when he became draftsman on preliminary location surveys for the Great Northern Railway Company. In January, 1910, he became draftsman on maintenance, location, and construction and later served for a short time as transitman for the Oregon and Washington Railway Company. In May, 1910, he went with the Alaska Northern Railway Company as chief draftsman, in charge of the compilation of surveys and estimates for the Alaska Central Railway. In October, 1910, he became draftsman on construction with the Oregon-Washington Railroad and Navigation Company.

Francis Fitzpatrick, the young engineer, left railroad work in August, 1911, to take a position with the Isthmian Canal Commission, and he was successively in charge of construction of two reinforced-concrete retaining walls, the construction of all concrete work at the Pedro Miguel locks of the Pacific Division, and transitman with the First Division in charge of the installation of all lock and gate operation machinery for the Pedro Miguel and Miraflores locks. He later had charge of construction of seacoast fortifications for the Panama Canal and Pier No. 7 for the Panama Railroad. In May, 1916, he left the Canal Zone to take charge of construction of seacoast fortifications at Fort Rosecrans, California, which assignment was completed in May, 1917.

Francis Fitzpatrick, the engineer, qualified for and was commissioned a Captain in the Engineer Reserve Corps of the U. S. Army on February 23, 1917. He was called to active duty on May 8, 1917. Thereupon he reported to assignments as follows: May 8, 1917, presidio of San Francisco; August 29, 1917, Camp Lewis, Washington; November 1, 1917, Camp Pike, Arkansas; and January 23, 1918, American Expeditionary Forces, France. While in France he served as follows: August 15, 1918, Company Commander in 316th Engineer Training Regiment; August 30, 1918, in the office of the chief engineer of the 1st Army, as assistant army roads officer; and November 1, 1918, Company Commander in the 508th Engineer Regiment. He returned to the United States and on June 16, 1919, was stationed at Camp Shelby, Miss., with the 508th Engineer Regiment. The regiment was demobilized and Captain Fitzpatrick was honorably discharged from the service on July 23, 1919.

On July 1, 1920, Captain Fitzpatrick was again commissioned in the U. S. Army, this time as a Captain in the Coast Artillery Corps. Thereupon he reported to assignments as follows: November 27, 1920, on harbor defense works at Puget Sound, with the 14th Coast Artillery, Fort Worden, Washington; September 13, 1923, at Fort Monroe, Virginia, as student, Battery Officers' Course, Coast Artillery School; April 28, 1924, at Fort Stevens, Oregon, with the 14th Coast Artillery Regiment; June 20, 1924, at Fort Eustis, Virginia, with the 52d Coast Artillery Regiment; and on January 4, 1926, in Hawaii, with the 41st Coast Artillery Railway Battery.

Captain Fitzpatrick was transferred from the Coast Artillery Corps to the Corps of Engineers on July 9, 1926. He was assigned to the 3d Engineer Regiment in August, 1926, for service, again in Hawaii. On December 23, 1929, he was assigned to the U. S. Engineer Office, at Vicksburg, Miss., as assistant to the district engineer. While there he also had charge of the Organized Reserves of the 4th Corps Area and later was disbursing officer for the Mississippi River Commission. On July 4, 1932, Captain Fitzpatrick was transferred to Cleveland, Ohio, as instructor for the Ohio National Guard (112th Engineer Regiment), Organized Reserves of the 5th Corps Area. In the spring of 1933, he was construction officer, Civilian Conservation Corps, in Ohio and West Virginia. He was stationed at Chicago on temporary duty with the Civil Works Administration for Cook County, from January to July, 1934. Captain Fitzpatrick was promoted to Major, Corps of Engineers, on August 1, 1935. He was assigned to temporary duty as consulting field engineer with the Works Progress Administration in Philadelphia, Pa., in October, 1935. He was umpire for the 2d Army Maneuver, Fort Knox, Kentucky, in July and August, 1936.

Major Fitzpatrick became assistant to the district engineer, U. S. Engineer Office, in Pittsburgh, Pa., on September 1, 1936. He was on detached service with the Works Progress Administration at Los Angeles, Calif., from October, 1937, to April, 1938, whereupon he resumed his duties at Pittsburgh as chief military assistant to the district engineer.

Major Fitzpatrick was assigned as Professor of Military Science and Tactics at Oklahoma Agricultural and Mechanical College, at Stillwater, Okla., and was to have reported for duty on August 1, 1939. On July 15, 1939, he was en route, with a government chauffeur, to the Tionesta Creek flood control dam, under construction under the supervision of the Corps of Engineers, near Tionesta, Pa. He was particularly interested in construction, highway, and railroad problems in relation to this project. The assignment which required a journey to Tionesta was to have been his last one in the district prior to his transfer. The car in which he was a passenger was struck near Bakerstown, Pa., by another car which came, out of control, from the opposite direction. The occupants of the government car were fatally injured, and Major Fitzpatrick died on July 16, 1939. Before he died he regained consciousness long enough to identify himself and to exonerate the chauffeur of any blame whatever for the accident. Interment was made in the Arlington National Cemetery, Virginia.

The career of Major Fitzpatrick came to a close in the line of duty. He would have had it so. He had been a young railroad engineer from March, 1905, to August, 1911; a government engineer on construction, much of the time in the Panama Canal Zone, from September, 1911, to May, 1917. His service to his country as an army officer began in May, 1917, and ended in July, 1939, a long and honorable service. His profession took him to numerous places, many of which were hazardous. While in France, during the World War, he served in the Defensive Sector (Toul), Seichprey, Xivray, St. Mihiel, and Meuse-Argonne. However, it was a tragic accident on a peaceful countryside that caused his untimely death.

While in the Pittsburgh Engineer District, Major Fitzpatrick served as executive officer. He supervised and correlated, for the district engineer, the numerous civil and military activities of the District. He was an expert on labor conditions and relations as well as regulations relating to Federal projects. It was this particular qualification which led to his being called to temporary duty with the Works Progress Administration at Los Angeles. He was particularly interested in the many engineering problems relating to river and harbor and flood control and protection activities. He was firm in his military duties, but of genial disposition and considerate of all with whom he came in contact.

Major Fitzpatrick was married at Cashmere, Wash., to Jane Ethelyn Clark who, with a daughter, Anne Katherine, and two sons, Francis James, Jr., and Robert Clark, survives him.

Major Fitzpatrick was elected an Associate Member of the American Society of Civil Engineers on October 1, 1913.

HARRY J. HANMER, Assoc. M. Am. Soc. C. E.[1]

DIED MAY 4, 1939

Harry J. Hanmer, the son of Charles and Emma (Crim) Hanmer, was born at Jordanville, N. Y., on December 6, 1881. His preliminary education was received at Jordanville Union School and Richfield Springs High School, after which he entered the College of Applied Science, Syracuse University, Syracuse, N. Y. In June, 1906, he was graduated from the University with the degree of Civil Engineer.

His first assignment was that of inspector on the construction of a sewage system for the Village of Mohawk, N. Y.; and in December, 1906, he entered the employ of the Remington Typewriter Company at Ilion, N. Y., as a draftsman.

Mr. Hanmer was appointed assistant city engineer of Gloversville, N. Y., in March, 1907, and in October, 1913, he became city engineer.

During his long and faithful service with the City of Gloversville, Mr. Hanmer was engaged in the design, construction, and maintenance of city streets, sewers, and the sewage disposal plant. He was in immediate charge of the Gloversville Sewage Experimental Station and of the construction of the Gloversville Sewage Disposal Plant which covered 10 acres and cost $250,000.

In addition to his extensive activities as city engineer, Mr. Hanmer was the author of several articles, one of which was entitled "The Construction and Operation of the Gloversville Sewage Disposal Plant" which has been widely read by sanitary engineers.[2]

On October 23, 1913, he was married to Mabel R. Peck of Gloversville, N. Y. He is survived by his widow, his father, and a sister, Mrs. R. D. Belshaw.

Mr. Hanmer was a member of Phi Gamma Delta Fraternity; the First Methodist Episcopal Church and a member of the Official Board; the Young Men's Christian Association (Y. M. C. A.); the Benevolent and Protective Order of Elks; the Masonic Order, Mohawk Valley Lodge; the New York State Association of City and Village Engineers; the Eccentric Club; the Pine Brook Country Club; and the Republican Club.

Mr. Hanmer was endowed with an attractive personality; his friends were legion in his professional life as well as in the activities of the several social organizations in which he was greatly interested. He was particularly active in church work and in the Y. M. C. A.

He was an indefatigable worker and accomplished each task with diligence and extremely careful endeavor. With these exacting qualities of mind, Mr.

---

[1] Memoir prepared by John A. Wallace, M. Am. Soc. C. E.

[2] *Engineering News*, Part 1, Vol. 74, No. 16, October 14, 1915, p. 744, and Part 2, Vol. 74, No. 17, October 21, 1915, p. 780.

Hanmer retained the esteem and affection of his associates during his entire professional career.

Mr. Hanmer was elected an Associate Member of the American Society of Civil Engineers on October 1, 1912.

HAROLD FREDERICK JANDA, Assoc. M. Am. Soc. C. E.[1]

DIED JULY 29, 1939

Harold F. Janda was born on April 21, 1893, in Portage, Wis. His father, Anthony J. Janda, a printer, had emigrated from Bohemia. His mother, Katherine (Sitterly) Janda, was a native of Madison, Wis. Besides Harold, the family circle included an elder sister, who died in 1920.

The boy attended the public schools of Portage and then entered Carroll College at Waukesha, Wis. A desire for an engineering training caused him to transfer to the University of Wisconsin, at Madison, which he entered as a sophomore with advanced standing. He was graduated in 1916 with the degree of Civil Engineer. He was a good student, but the record shows that one of the poorest grades he received was in highway engineering, the subject which he later taught for many years in the same college.

During the summer following graduation he worked as assistant engineer for the Baraboo Drainage Commission. In the fall he received an appointment as instructor in civil engineering at the University of Cincinnati, at Cincinnati, Ohio, under the late Dean Herman Schneider, Assoc. M. Am. Soc. C. E., who was introducing his famous cooperative system under which the engineering student spends alternate periods in the school and on the job. It was part of Mr. Janda's duty to supervise the work of the students on the job.

The future seemed secure enough to the young instructor to justify matrimony, so he and Margery I. Sawyer, of Menominee, Mich., were married before the end of 1916.

In 1919, Mr. Janda was made an assistant professor at Cincinnati and continued in that position until he went to the University of North Carolina at Chapel Hill, N. C., in 1921 as associate professor of highway engineering. There he found opportunity for research in the field of vertical earth pressures and, as a result of his work, was called to Washington, D. C., in 1924, to serve as associate director of the Highway Research Board of the National Research Council. The university granted him leave of absence for this service. In 1926 he returned to the University of North Carolina as professor of highway engineering and head of the department of civil engineering.

Professor Janda was called to the University of Wisconsin, his alma mater, in 1928, as head of the department of highway engineering and city planning, and served continuously until his death.

---

[1] Memoir prepared by L. F. Van Hagan, M. Am. Soc. C. E.

Through his study of vertical earth pressures, Professor Janda had become interested in the characteristics of soils as they affect engineering work, and the study of soils remained one of his major professional interests. At the time of his return to Wisconsin, in 1928, the Wisconsin Highway Commission was having much difficulty with the phenomenon known as frost boils. Professor Janda was called upon to investigate the problem for the commission and became a recognized authority on soil conditions and characteristics in Wisconsin. From 1929 until his death, he served the commission frequently as a consultant upon a wide range of problems.

Frequently called upon for service on various public committees Professor Janda gave liberally of his time and energy in that work. His familiarity with city planning and zoning and with traffic problems made him an effective worker on such committees. He was open-minded and forward-looking, but always kept his enthusiasms and emotions under control. His ability to visualize the practical possibilities of a situation gave weight to his contributions in council.

He was proud of his profession and was active in promoting its interests. His services were recognized, in 1935, when he was made president of the Engineering Society of Wisconsin. A heart attack at Christmas time in 1935, however, made it impossible for him to preside at the spring meeting of the society in 1936.

Professor Janda liked to teach. He liked the students and enjoyed his contacts with them. He held them to a high standard of performance but was always even-tempered, courteous, and reasonable. His teaching was fresh and stimulating because of his close contact with technical problems in the field. He was deeply interested personally in those problems, seeking to understand them and to find practical solutions. His thesis students (and they were numerous) had the satisfaction of feeling that they were making genuine contributions to professional knowledge, a feeling that was reflected in their earnestness and enthusiasm. He had them out on the job in all parts of the state gathering their data and testing their findings in the "fiery furnace" of practice. His classroom teaching likewise was vibrant with his interest in his subject and the freshness of his material. He prepared carefully for each class period and organized his material with great skill.

An interest in semiprecious stones was Professor Janda's chief hobby. His interest was a scientific one, and he was skilled in the identification of gems. His modest collection was full of interest and furnished material for many an address at student gatherings.

Professor Janda was a member of the honorary societies of Sigma Xi, Chi Epsilon, and Tau Beta Pi. In politics, he was a believer in the American system and could probably have been classed as a liberal conservative. He attended the Episcopal church.

His family, consisting of two daughters, Barbara Sawyer, and Nadia Ann, received much of his attention. His widow and their two children survive him.

In his contacts with people, Professor Janda was frank, easy, and modest. Those who were intimate with him found him to be well-informed in a wide range of subjects. He was an interesting talker, and his cheerfulness and good nature made him a delightful companion.

Professor Janda was elected an Associate Member of the American Society of Civil Engineers on June 7, 1926.

WILLIAM JOSEPH JUDGE, Assoc. M. Am. Soc. C. E.[1]

Died June 30, 1939

William Joseph Judge was born in Hickman, Ky., on April 29, 1878, the son of Henry C. and Julia (Burke) Judge. He received a high school education at Hickman College, at Hickman, Ky. Later he took a course in mechanical engineering with the International Correspondence Schools at Scranton, Pa.

Although little is known about his boyhood days, it was then that his lifelong interest in dredging was inspired. His diversion was to sit on the banks of the Mississippi River which flowed near his home and watch the crews of the giant government dredges deepen the channels and build the levees. He determined then and there that dredging was to be his life work.

Although a year younger than the required age he left home to enlist in the 3d U. S. Volunteer Engineers in the Spanish-American War. He was practically disowned by his father for joining up with the "Damnyankees." However the same father was very proud of his son when he returned as a Sergeant in Company "L."

Immediately after his discharge from the Army, in 1899, he began his work with dredges as a clerk with the Mississippi River Commission on the dredge fleet at Memphis, Tenn. He rose to the grade of foreman in 1902. Then he went with the Atlantic, Gulf and Pacific Company as paymaster and assistant superintendent on work at Vicksburg, Miss., Mobile, Ala., Tampa, Fla., New Orleans, La., and Pascagoula, Miss., and at the Isthmus of Panama where the company erected dredges for the Isthmian Canal Commission until 1907. He then went with the Canal Commission as dredge master until 1910.

From April, 1910, to May, 1917, he was field superintendent with James Stewart and Company and the American Pipe and Construction Company on New York State Barge Canal work, which included dredging, subaqueous drilling, blasting, and rock removal.

In May, 1917, he enlisted for service with the United States Army in the World War. William Judge, previously having received a commission as First Lieutenant of Engineers, was ordered to camp in the spring of 1917. First he was at Madison Barracks, then at Camp American University at Washington, and for a short time at Camp Belvoir, Virginia. At the end of the training period, a very few of the more meritorious were given commissions of higher rank. Among these was Lieutenant Judge, who was commissioned a Captain. He was assigned with thirty others to the 303d Engineers, the Engineer Regiment of the 78th Division, in training at Camp Dix, New Jersey. Captain Judge was put in command of Company " F." Due to the excellent service record of this company, the Commanding Officer of the Regiment, Col. E. M. Markham, M. Am. Soc. C. E., who later became Chief of Engineers, selected Captain Judge for early promotion, made him a Major, and placed him in command of the Second Battalion. He was in charge of troops on the British ship on which they sailed. They landed in England and shortly thereafter went to France and trained behind the lines in the British sector. The Division was brigaded with the British on the northern sector of the front for some time, but moved to the American sector about July, 1918.

---

[1] Memoir prepared by R. H. Keays, M. Am. Soc. C. E.

The Division was in reserve in the St. Mihiel attack, and relieved two regular divisions after the attack, taking over a large sector of the front line. Later the Division was moved to the Argonne where it was held in reserve during the big attack but after the attack it replaced the 77th Division. They occupied the front line, including Grandpré and the region to the east, until shortly before the Armistice. When the last big drive was made the Division led in the attack and was only relieved a day or so before the Armistice.

The Regiment moved into winter quarters after the Armistice and remained in France until the following spring. The men came home about June, 1919. In the meantime Major Judge had been promoted to Lieutenant Colonel and came home in command of the Regiment.

From July, 1920, to May, 1923, Colonel Judge was back with his dredges as field manager for A. H. Cipriani on the Caroni Reclamation Project and Orapouchee Lagoon on the Island of Trinidad.

He returned to the New York State Barge Canal in 1924 and remained until 1926. This time he was field superintendent for The Empire State Dredging Corporation. This project also included much drag-line work.

As field superintendent for the T. T. Sweet Dredging Company of Miami, Fla., in 1927 and 1928, Colonel Judge did dredging for land reclamation. While there the great hurricane of 1927 made much trouble for his dredges.

From 1928 to 1930, Colonel Judge was field superintendent for the National Dredging Company in charge of dredging on the Hudson River and Kings Park, Long Island, New York.

Early in 1930 his old war time comrade, Col. Roy W. Gausmann, M. Am. Soc. C. E., general manager for John Monks and Sons and Ulen and Company in Greece, induced Colonel Judge to come to Macedonia on the Struma project. In this capacity Colonel Judge's career was noteworthy. In Macedonia there was nothing with which to begin—no organization, no plant, no trained men. The project was flood control, land reclamation, and irrigation in the Struma Plain, the drainage of the Pravi Marsh in the Plains of Philippi, and miscellaneous other work. The estimated cost was about

$20,000,000, which would have been about twice as much in American money. The company established their headquarters in Serres, Macedonia, a city of about 30,000 people.

More than $2,000,000 worth of equipment was bought in England, Germany, Holland, and the United States, including five large drag-lines, three large hydraulic dredges, a dipper dredge, many small drag-lines, and an excavating machine. The orders for plant were distributed by the Greek Government in this way, for diplomatic reasons. Men were brought from America, England, and Germany to operate the plant. It was necessary to redesign the dredges in Macedonia. Camps, roads, and bridges were built as well as railroads, machine shops, docks, and launching pits.

After a year or so the dirt began to move in ever increasing quantities so that in the end about 80,000,000 cu m had been handled. Long before the work was completed all the foreign operators had been replaced by native Greek operators trained on the job.

The most exciting times of Colonel Judge's stay in Macedonia, however, were his experiences in the attempted revolution of 1935. The project was started under the Liberal Government of Venizelos and most of the inhabitants of Macedonia were Venizelists. In 1933, however, the Royalists obtained control of the government under Tsaldaris and General Kondylis.

A revolutionary movement was started in 1935 in Macedonia with headquarters in Serres. This was very embarrassing for Colonel Judge and the companies he represented, for most of the employees were Venizelists.

All communications were soon cut off from the outside world and from the companies' main office in Athens, Greece. The companies' transportation equipment and telephone system were seized by the revolutionists. Bombs were dropped in the city by Royalist aviators and the city was full of troops on their way to the west to their defense lines along the Struma River. On the advance of the Royalist troops, however, the revolution quickly collapsed and the Royalists took over the surrounding territory.

Colonel Judge has been commended highly for the diplomatic skill with which he maintained absolute neutrality in handling the delicate situation and the affairs of his employers during the trying period.

While still in Macedonia, Colonel Judge became seriously ill in the summer of 1936. He was taken to Vienna, Austria, for treatment. His health did not improve, however, and in January, 1937, he was brought to the United States to his home in Cooperstown, N. Y., where he died on June 30, 1939. Funeral services were held from Christ Church in Cooperstown, and he was buried in Lakewood Cemetery.

William Judge was a Colonel in the Engineer Reserve and a Charter Member of the Society of American Military Engineers.

On April 28, 1917, Colonel Judge was married at Cooperstown to Margery Bunn, who survives him.

Colonel Judge was elected an Associate Member of the American Society of Civil Engineers on August 13, 1934.

ARTHUR SYLVANUS KEMMAN, Assoc. M. Am. Soc. C. E.[1]

Died October 31, 1939

Arthur Sylvanus Kemman was born at New Hampton, Iowa, on August 30, 1886, the son of Alvino Kemman and Louise (Schert) Kemman. His father was county engineer of New Hampton for many years.

Mr. Kemman was graduated from the New Hampton High School, the valedictorian of his class. He attended the U. S. Naval Academy, Annapolis, Md., from June, 1904, to May, 1908, and spent two years at sea. For two years subsequent to this period he assisted his father on various engineering projects at New Hampton. In September, 1912, he went to California where he worked for slightly more than a year on plant and structural design for the Colton Cement Company. The next four years he was employed as draftsman by the California State Highway Commission.

He went to Washington, D. C., in May, 1916, and compiled specifications for ships in the Bureau of Construction and Repair, Navy Department. Between April and December, 1917, he was employed in the capacity of general assistant to the superintendent constructor, U. S. Navy, on submarines L-6 and L-7 at the Long Beach (Calif.) Shipbuilding Company. Mr. Kemman assisted on trial runs and inclining experiments during this assignment.

In December, 1917, he received an appointment as Lieutenant in the U. S. Naval Reserve Force, and was sent to the U. S. Navy Yard at Bremerton, Wash. His assignment there included duties as office superintendent and material officer. He supervised requisition and inspection of materials and supplies for industrial plants, and inspected and valued the vessels taken over by the Navy. This appointment terminated in October, 1919, and Mr. Kemman immediately secured the position of marine inspector for the Union Oil Company. Here he supervised construction of tank steamships at the Southwestern Shipbuilding Company in San Pedro, Calif., until May, 1921. Following this came a period of private practice in surveying and land subdivision work.

He was employed from 1922 to 1925 as draftsman by the Southern California Edison Company at Los Angeles, Calif. Subsequently he spent a short time as Junior Civil Engineer with the Storm Drain Design Division, City Engineer's Office, at Los Angeles.

In July, 1925, he took a position as draftsman with the Los Angeles County Flood Control District and remained with this organization continuously until his death. His work was quite varied. After assisting in designing some of the first structures constructed by the District, he transferred to the Hydrographic Department shortly after its inception in 1927 and was active in the expansion of this work. He was particularly interested in the conception and extension of the District's mountain telephone lines and radio system and served for a period as head of the Communications Department. Mr. Kemman was a very capable engineer in any work assigned, and was an excellent draftsman. He was very active in all employees' affairs and popular with his fellow engineers.

---

[1] Memoir prepared by Walter J. Wood, Assoc. M. Am. Soc. C. E.

Mr. Kemman served as secretary and president of the Naval Academy Alumni Association at Los Angeles. He was a member of the William H. Upton Naval and Military Lodge, No. 206, Free and Accepted Masons; Post 457, American Legion, and served as Commander during the year 1938–1939; the American Association of Engineers and Architects; the Southern California Historical Society; E. Clampus Vitus; and the Los Angeles Yacht Club. His principal diversions were golf, yachting, and tennis.

The promotion of the Ross-Loos Clinic in Los Angeles for the benefit of public employees was aided by Mr. Kemman. He gave freely of his time in assisting the organization of the Los Angeles Civic Center Employees Federal Credit Union and served for many months as the first Secretary-Treasurer, without compensation, to get the Union going.

Personally, Arthur Kemman was a kindly, generous, considerate gentleman. He made friends easily and was ever ready to do them a favor.

He was married to Ruth Holly of Westfield, N. Y., on October 21, 1913. He is survived by his widow, two sisters, Martha Kemman and Elva Kemman (Mrs. James E. Bezpalec), and a brother, Alvin Kemman.

Mr. Kemman was elected an Associate Member of the American Society of Civil Engineers on April 15, 1929.

JOHN KYLSTRA, Assoc. M. Am. Soc. C. E.[1]

DIED MARCH 18, 1939

A long way from the pastoral scene of his boyhood, dependent entirely on his own energy and resources for his advancement, John Kylstra entered "on the ground floor" an industry that he grew to love, and grew with it to a position at the top of his profession, as chief engineer of the Boeing Aircraft Company.

The son of the Rev. S. C. Kylstra and Mrs. A. V. (Willebrands) Kylstra, Jack was born on February 3, 1895, in Engleum, The Netherlands. He attended grade school in four or five different villages in the land of dikes and windmills, clumping in wooden shoes along the country roadways to school. Then he graduated to leather shoes to receive his secondary education in the city school of Leeuwarden, Province of Friesland.

One day in 1913 the taste of an imported Yakima (Wash.) apple enticed the elder Kylstra to consider moving to the United States, and four weeks later the family arrived in the Yakima Valley. For five years Jack helped with the irrigating and marketing of crops, while his younger brother finished high school in Yakima and prepared for college.

---

[1] Memoir prepared by Robert J. Minshall, Esq., Seattle, Wash.

Jack's eye, too, turned toward higher education, and he forthwith took his Holland school records and a few choice compositions to the registrar at the University of Washington, Seattle, Wash., where he was at once enrolled.

He was graduated from the University in 1922 with a Bachelor of Science degree in civil engineering. His industry and aptitude had won him a *cum laude* rating with his degree, and membership in Sigma Xi, science honorary fraternity, and Tau Beta Pi, engineering honorary fraternity.

Promptly came Mr. Kylstra's opportunity to put his engineering training to work. He joined Lovsted and Company, a railway material firm of Seattle, in August, 1922, working afternoons for four months and then full time until September, 1923. As production manager of the firm, his job included the drafting and design of gears, bearings, etc., for logging locomotives and sugar plantation equipment.

From September, 1923, to October, 1924, he was a fieldman for the Pacific Telephone and Telegraph Company in Seattle. He served as instrumentman, was in charge of small maintenance projects, and prepared estimates on larger projects.

After these two years of varied experience, in October Mr. Kylstra joined the Boeing Aircraft Company of Seattle and was assigned to the stress section of the engineering department. He began checking the structural strength of the big PB-1 patrol boat that was being developed for the U. S. Navy. He became known for alert resourcefulness, meticulous attention to details, and dependability, and before long he was advanced to chief of the stress section. In this work he became thoroughly acquainted with airplane construction of all types common to the period.

In 1929 Mr. Kylstra was made project engineer for a new type airplane that proved to be far more significant in the advancement of aviation than even its makers anticipated. It was the Boeing Monomail, first successful all-metal, smooth-skin, monoplane transport, incorporating retractable landing gear and the streamlining that has since become an inherent feature of modern airplane design.

Upon the successful conclusion of this assignment he became project engineer of the XP-936 experimental pursuit plane for the U. S. Army, a type that proved as significant to the pursuit airplane field as the Monomail was to the air transport field. The XP-936 was the forerunner of a long series of high-speed Boeing low-wing monoplane pursuits known as the P-26 type pursuit planes widely used by the U. S. Army Air Corps. Subsequently, Mr. Kylstra served as project engineer for the YP-29, an advanced type experimental pursuit plane, and the XF7B-1, an advanced fighter airplane built experimentally for the U. S. Navy.

In 1934 Mr. Kylstra was called upon to "shoulder a job" that was to measure the fullest capacities of the man. The Boeing Company had contracted to build experimentally for the Army Air Corps a four-engine bombardment airplane far larger than any previously conceived—the now-famous Boeing

XB-15 Super Flying Fortress. It was a project actually started before the development of the smaller B-17 type Flying Fortress, but because of its scope, it required substantially more time for completion. At the helm of this secret project was Jack Kylstra in his familiar rôle as project engineer. Directly or indirectly, he had his finger on some 315,000 man-hours of engineering time that went into the development of the 35-ton super ship, now the largest landplane in service in the world and holder of two official international aviation records, one for maximum load-carrying and the other for speed with a pay load of 2,000 kg for a distance of 5,000 km, or 3,100 miles.

With his wide experience in the military airplane field, Mr. Kylstra, in 1937, advanced to become engineer in charge of all military projects for his company. As such he was overseer of work on the initial fleet of B-17B Flying Fortresses produced for the Army Air Corps, and was a frequent commuter between the Seattle factory and Wright Field in Dayton, Ohio, where the Air Corps Matériel Division is located.

It was in Dayton that he met Peg Luetta Platte, who became Mrs. Kylstra on October 9, 1938.

Mr. Kylstra became chief engineer of the Boeing Aircraft Company on January 1, 1939, while the company was in the midst of producing and testing its various new types of large four-engine airplanes for both commercial and military service. This was his position at the time of his death.

John Kylstra was elected a Junior of the American Society of Civil Engineers on July 9, 1923, and an Associate Member on June 6, 1927.

JOHN RAYMOND LAPHAM, Assoc. M. Am. Soc. C. E.[1]

DIED OCTOBER 2, 1939

John Raymond Lapham was born at West Medway, Mass., on April 1, 1886, the son of Frank D. and Alfarata (Scott) Lapham. His family was of old New England stock on both sides. He attended public school and determined to have a college education. By dint of hard work and "stick-to-itiveness" he managed to put himself through Brown University, at Providence, R. I., where he was graduated with the degree of Bachelor of Science in Civil Engineering in 1909. He had only moderate help from home, and this fact influenced him throughout his life in his attitude toward those who were always asking others for help. "Help," he would say, "help? I helped myself. Why can't you?" And then, after laying down the law in no uncertain terms, and denouncing the human race in general and particular, he would help, aid, and assist all sorts and conditions of men.

At college he was an average student; the acclaim and honors that went to the brilliant man meant nothing to him and he simply did not try to achieve what seemed to him unnecessary merit. He did his work passably well and was entirely satisfied. Also he was always more than glad to help his fellows with their studies and took no end of satisfaction when they received more credit than he did himself. In the classroom, when he was in the proper mood, his innate ability would suddenly shine and as quickly disappear, as once when he had a special assignment in mechanics and acquitted himself so remarkably that his fellow students were aghast and the professor could only give the infrequent recognition, "Very good!"

---

[1] Memoir prepared by J. S. Crandell and Sydney Wilmot, Members, Am. Soc. C. E.

Some things in his college life were not learned from books. Perhaps the outstanding relationship of his last year, at least to judge by the repeated references that he and other "old grads" were wont to make, was a certain hilarious group meeting familiarly known as the "42 Hope" club. This was named after the room in which the club met irregularly, but frequently and protractedly, as the demands of the college schedule permitted. The group confined itself diligently and boisterously to research into the ancient, if not honorable, game of "penny ante." Most if not all of the members were senior civil engineers and all have made subsequent favorable records, including half a dozen now members of the Society.

Upon graduation John Lapham "got a job" with the New York, New Haven, and Hartford Railroad Company. He liked the work fairly well, but thought he could do better at teaching, although there was no one in his family who ever had devoted his or her life to the profession. After two years of railroad life, during which he proudly announced that he learned much more about straight flushes and full houses than he did about engineering, he "got a position" as instructor in civil engineering at The Pennsylvania State College, at State College, Pa.

It is no secret that many of his acquaintances were a bit dubious about his prospects of success in this new work. To his intimate friends, however, the issue was never in doubt, for they recognized only too well the real ability that lay behind his simple and rather offhand manner. The fact was that after a period of intellectual drifting he was about to "set sail" seriously for a definite "port" in the educational world. Within the short space of fifteen years he was to become Dean of an important engineering school.

In those days of the early nineteen hundreds the life of a faculty member at the State College was particularly rough and tough on those whom the students did not like. But they took to "Lap" immediately; and he was equally popular with the faculty. He was appointed to numerous committees and attended many a conference that many older men never even knew about. Yet no one ever became jealous of him. His methods were always "open and above board," so that not a shred of envy clouded his colleagues' minds—a rather remarkable experience in a college community.

Seeking more rapid advancement, in 1916 he went to George Washington University, at Washington, D. C., to serve as assistant professor of civil engineering. He soon became professor, and eventually, in 1926, he was made, first, Acting Dean of the College of Engineering, and Dean, a year later. In these positions he became acquainted with many of the leading men of the country, and, because of the favorable circumstances that only the Capital can afford, he met various prominent engineers from all over the world. This was of benefit alike to himself and to his classes.

He did considerable consulting work both for the manufacturer as well as the user of portland cement. His duties as Dean, however, prevented him from giving as much of his time to such work as he otherwise might well have done. In addition, he was made a member of the Board of Zoning Adjustment of the District of Columbia. In this he was particularly well fitted to take an active part, for one of his peculiarities was his inborn ability to " see quite through the deeds of men." Consequently, when obstreperous Washington real-estate manipulators tried to force some piece of chicanery past the Board, Mr. Lapham instinctively put his finger on the iniquity and checked it.

From his father, Dean Lapham inherited the gift of telling stories. His classroom work sometimes was largely devoted to the relating of yarns that were apropos of the subject under discussion. The students absorbed these tales, and increased their own knowledge out of all proportion by remembering what had been told them in so entertaining a manner. He was very careful never to exaggerate, yet the stories lost nothing in his telling. He never knew that he gave instruction in such a manner; it simply was just natural for him to do so.

His fund of anecdotes for social gatherings was almost limitless, and his ability to play jokes on others was amazing. Often his friends woke up, long afterward, to the fact that they had been the objects of the tricks; but there was no resentment. " Oh, that was just Lap again," would be the inevitable remark.

His railroad experience, plus a New England conscience, gave him as astonishing a command of well-nigh irrepressible expletives as any American other than Mark Twain ever loosed upon his friends. And he would " cuss out " the preacher to his face as eloquently as if he were the garbage man. It was all the same to Dean Lapham so long as he thought the person addressed needed it. These were no common, ordinary, everyday, over-used " cuss words," however; they were vibrant, cogent, exhilarating phrases, the like of which have seldom been heard before. One prominent structural engineer, a member of the Society, spent an entire afternoon trying to repeat, with suitable tones, a particularly novel example that the Dean had used with marked effect, only to give up finally and say, " Well, only Lap could say that and get away with it." Needless to say, the students knew nothing of this hidden gold mine of humor, for humor it was. But the outside world frequently was exposed to its fury.

Probably few of his colleagues knew that he had no use for structural engineering. To him it was a branch of the civil engineer's work that he supposed had to be carried on by somebody, but he was certain that that somebody would not be he. He was greatly interested in sewage disposal, water supply, and concrete testing. He made numerous trips about the country examining works of this character—usually the whole family drove together—and he was planning on writing a book concerning them. He was temperamentally unsuited to be an author, however, because he had too much caution to write. He would talk very freely, if no reporters were present, but almost never would he put his remarks on paper. Hence, he never wrote a book, in which respect he differed from most of his fellows.

He took his work as Dean very seriously as regards both students and faculty. He thought that he owed it to the students to supply them with incentives for further study, for perfecting themselves in their chosen field, and for high scholarship. His faculty members always had "a friend at court," because he would battle for his men with much greater aggressiveness than he would for his own personal advancement. The students always found him to be just. There was never a suggestion of favoritism in any of his decisions. The faculty knew he had a sympathetic ear, and that their troubles were his. In spite of a forthrightness that was inborn, Dean Lapham developed the utmost of tact in dealing with those college situations that frequently become "ticklish." He was careful not to stir up animosities. Beyond that, his fairness, his generosity, and his hospitality were bywords. As a result the administrative side of his deanship was remarkably free from misunderstandings and heartrendings. It was a genuine success.

He hated all pretence and sham. The engineer in practice who failed to give a good account of himself felt Dean Lapham's vituperative denunciations most severely. He was painfully honest himself, and he expected that same quality in others if they were engineers. "If they are not honest, let them try something other than engineering," was his slogan.

In 1916 he was married to Evelyn M. Ayres, secretary of the civil engineering department at The Pennsylvania State College. In so doing he showed the same keen judgment that marked his dealings with men. By virtue of conscientious team work their home life typified everything that intelligent people are supposed to attain. Almost all of it was in Washington, at first in an apartment, then in a small house of their own, and eventually into a more spacious home, where Dean Lapham lived for the last ten years. There could be found students, neighbors, relatives, out-of-town friends—it was continuous "open house." No home could have been more profitably used.

In the home was real hospitality and in the hearts of the Dean and his family there was much genuine friendship, the kind that showed itself in many concrete acts of kindness or beneficence, as many a needy student found out to his satisfaction. It was only natural that many friends should congregate there, where one was sure to find good fellowship, good food, good books, and good fun. On the frequent occasions when the Dean would set out on a foraging expedition for the family, he was almost sure to return with a bouquet of flowers, if nothing else. He loved them, although not himself particularly fond of gardening.

Dean Lapham was a member of Acacia fraternity, in which he took great interest. He was an early member of Sigma Tau, an honorary engineering fraternity; a member of the Washington Society of Engineers; the Society for the Promotion of Engineering Education; the American Concrete Institute; and the Charles River Lodge of Masons in West Medway, Mass. He was much interested in the Student Chapter of the Society at the University and served for a number of years as its faculty adviser.

Dean Lapham's sense of strict integrity was such that for many years he saw no need of affiliating with any church. As his own children were growing up, he faced the matter again with equal candor. He joined the Methodist Episcopal Church. For years thereafter he was a loyal member and at various times an officer of the Hamline Methodist Church in Washington. In eulogizing him, his pastor gave this penetrating picture of his character:

> "He was not saintly, nor would anyone call him pious. But he was genuine, he was sincere, he was fair, he was generous, he was wholesome. In a word, he was just plain good—this jovial Dean."

The funeral service of Dean Lapham was a revelation, and a reflection of how great an investment of friendliness can be put into one abbreviated lifetime.

Thanks to his good constitution and abstemious habits, Dean Lapham enjoyed continuous good health. He died on October 2, 1939, after a week's illness, following an operation. He is survived by his mother, Mrs. Alfarata Lapham, and a brother, Mark Albert Lapham, both of West Medway, Mass.; also by his widow, Mrs. Evelyn Ayres Lapham; a daughter, Evelyn; a son, John Raymond, Jr.,

Dean Lapham was elected a Junior of the American Society of Civil Engineers on November 8, 1909, and an Associate Member on April 16, 1918.

HENRY AMBROSE LARSEN, Assoc. M. Am. Soc. C. E.[1]

DIED APRIL 1, 1939

Henry Ambrose Larsen was born at Manistee, Mich., in 1884. His early education was received in the grade and high schools at Manistee. In 1906 he was graduated from the University of Michigan at Ann Arbor, Mich., with the degree of Bachelor of Science in Civil Engineering, and immediately accepted a position with the Great Lakes Engineering Company at Detroit, Mich.

In 1908 he headed for the Pacific Northwest. In Portland, Ore., he accepted a position with the firm of Doyle and Beach, handling their structural engineering work. Many of the older steel frame structures in this city are the result of his endeavors.

Mr. Larsen was married to Alice Gregory, in Bay City, Mich., on January 18, 1911, and returned with his bride to Portland.

In 1915 he accepted a position with the L. A. Norris Company at San Francisco, Calif., and in 1918 was transferred to the Los Angeles (Calif.) office as manager. During these years he became identified with the sale and distribution of "Clinton" electrically welded fabric. When the Wickwire

---

[1] Memoir prepared by Cris Cron, Esq., Los Angeles, Calif.

Spencer Steel Company decided to merchandise this commodity in 1919, Mr. Larsen transferred to the Wickwire Spencer organization.

In the early 1920's he accepted a position with the National Steel Fabric Company, a subsidiary of Pittsburgh Steel Company, as its Pacific Coast Manager with headquarters in San Francisco. His duty was to merchandise "Steeltex" and Pittsburgh Fabric. His friends and competitors all agreed he did a most commendable job.

In 1933 he again became associated with the Wickwire Spencer Steel Company and in 1937 became the Pacific Coast Manager, a position which he occupied at the time of his death.

As an old business rival writes—

> "Heinie was a man's man, good to know, a worthy competitor with a sense of fairness and honesty and integrity in his relationships with others, which made him outstanding and respected among his business associates, friend or foe. The fabric industry of the Pacific Coast has been fortunate for two decades in having such a man in its midst and his passing will be sorely felt."

Mr. Larsen's sudden passing on April 1, 1939, in San Francisco, came as a shock to his associates of Wickwire Spencer Steel Company and his multitude of friends on the Pacific Coast, as well as in eastern circles.

He is survived by his widow and one daughter, Ethel (Mrs. John M. Evans).

Mr. Larsen was elected an Associate Member of the American Society of Civil Engineers on April 2, 1913.

DANIEL COLLINS LIPSCOMB, Assoc. M. Am. Soc. C. E.[1]

Died December 23, 1939

Daniel Collins Lipscomb was born in Fort Worth, Tex., on November 30, 1887, the son of William Lipscomb and Virginia Collins Lipscomb, who were both well-known educators in the South. The William Lipscomb School, a grade school in Dallas, Tex., is named for his father. His mother was principal of this school for many years. Mr. Lipscomb received his early education in the public schools of Dallas. Later, he entered the University of Texas at Austin, Tex., from which he was graduated in 1909 with the degree of Bachelor of Science in Civil Engineering.

From June, 1909, to September, 1909, he worked as a draftsman for the Chicago, Milwaukee and St. Paul Railway Company of Chicago, Ill. In September, 1909, he became an instructor at the University of Texas, teaching in the engineering department for one year. In May, 1910, he accepted the position of superintendent for the Standard Engineering and Contracting Company of Dallas, working on concrete bridge construction. In October, 1910, at the age of 23, he became assistant engineer for Hedrick and Cochrane, engineers of Dallas, in the construction of the Oak Cliff Viaduct, an outstanding feat of engineering at the time of its erection.

---

[1] Memoir prepared by a Committee of the Fort Worth Branch of the Texas Section consisting of W. O. Jones, Chairman, Joe J. Rady, Members, Am. Soc. C. E., and C. J. Harkrider, Jun. Am. Soc. C. E.

Mr. Lipscomb worked as assistant engineer on the Board of Engineers in charge of the Fort Worth water supply during the year of 1911. In 1912, he became resident engineer for the Southern Traction Company at Waco, Tex., in charge of bridge construction, but in 1913 went back to his job with the Board of Engineers as assistant engineer under Maj. John B. Hawley, M. Am. Soc. C. E., in the construction of the Lake Worth Dam. In 1914, he became engineer for J. C. Field, consulting engineer of Denison, Tex., and held this position until 1918 when he was employed as masonry supervisor for the Missouri, Kansas and Texas Railway Company of Denison.

Mr. Lipscomb resigned from this position to become city engineer of Durant, Okla., a position which he held for two years. He was in charge of supervising street paving, and sewer and water lines. Then, in 1921, he transferred his services as city engineer and water superintendent to the City of Denison, where he worked for two years. In 1923, he became an inspector for the United States Fidelity and Guaranty Company of Dallas.

In 1924, he worked for five months as assistant engineer for the Bureau of Public Roads and then worked the next five months as maintenance foreman of the State Highway Department of Texas. In April, 1925, he was employed by the American Road Company of Dallas as superintendent but gave up this position in December to become superintendent of streets for the City of Fort Worth, which position he held until his death. His work included the supervision, construction, improvement, and maintenance of all streets, and the supervision of garbage collection and disposal. He was a licensed engineer in the State of Texas.

Mr. Lipscomb was an excellent engineer and a man of fine personality and high ideals. He was highly esteemed as an efficient public servant and his loss is deeply regretted by his many friends.

He is survived by his wife, Frances (Wolfe) Lipscomb, to whom he was married in 1917. Mrs. Lipscomb was the daughter of Frank and Sarah Wolfe.

Mr. Lipscomb was elected an Associate Member of the American Society of Civil Engineers on August 31, 1915.

HARRY SEYMOUR McKIBBEN, Assoc. M. Am. Soc. C. E.[1]

DIED APRIL 12, 1939

Harry Seymour McKibben was born January 6, 1873, in Braceville Township, Trumbull County, Ohio. The eldest son of Seymour M. and Lydia (Smith) McKibben, he received his early education at the local schools of the township and the Newton Falls, Ohio, grade schools. He was graduated from Ohio Northern University, at Ada, Ohio, in 1896, and took postgraduate study at Wooster College, at Wooster, Ohio.

---

[1] Memoir prepared by Wendell P. Brown, M. Am. Soc. C. E.

Before graduation, and continuing until 1901, he was engaged in survey work during the summer, and teaching in the local country schools during the winter seasons. During 1901 and 1902, he taught school in Oklahoma, in addition to engineering and survey work for the Missouri, Kansas and Texas Railway Company and the Rock Island Railroad Company, and for irrigation projects in Oklahoma. From 1903 to 1905, he was engaged in survey work for the Baltimore and Ohio Railroad Company in Ohio, and as assistant county surveyor of Trumbull County.

From 1905 to 1909, Mr. McKibben was in private engineering practice in Trumbull County in charge of reservoir and contour surveys and all preliminary and field work in connection with the construction of three hydroelectric plants and about 18 miles of high tension lines of the Hydro-Electric and Gas Company of Warren, Ohio. He then served from 1909 to 1913 as county engineer in Trumbull County, and during 1914 and 1915 was city engineer at Warren. He was again in private engineering practice from 1916 to 1929, but acted as engineer for the Village of Newton Falls from 1929 to 1935. He returned to private engineering practice at Warren in 1935, and continued in this work until his death. While engaged in a field survey in the county, he suddenly passed away on April 12, 1939.

In addition to his professional practice, Mr. McKibben was interested in civic affairs, and served from 1922 to 1933 on the Board of Education of the City of Warren. He was also an active member of the Second Christian Church, and, among other activities, was a valued member of the church choir.

He was married on November 15, 1902, to Bertha Musson of Ligonier, Ind., who, with four sons, four daughters, and nine grandchildren, survives him.

He will be remembered as a conscientious and dependable engineer, a devoted husband, father, and grandfather, a worthy citizen, and one that recognized his obligations to the community and to his profession, and fulfilled them faithfully.

Mr. McKibben always had a deep interest in and appreciated his membership in the American Society of Civil Engineers, although he did not take an active part in its affairs. He was elected an Associate Member of the Society on December 2, 1914.

WILLIAM FRANKLIN MILLER, Assoc. M. Am. Soc. C. E.[1]

DIED DECEMBER 18, 1939

William Franklin Miller was born on June 21, 1880. He spent the earlier years of his life in Philadelphia, Pa., and came from a family that schooled him thoroughly along religious and civic responsibilities, and throughout his entire life he responded conscientiously to this earlier training.

---

[1] Memoir prepared by R. R. Nace, H. H. Garrigues, and R. G. Develin, Members, Am. Soc. C. E.

He obtained his engineering education from courses of the International Correspondence School, and through attendance at night classes of the Wharton School of the University of Pennsylvania, at West Philadelphia, Pa. In addition to these courses he was tutored by engineers working for the Pennsylvania Railroad Company, who were attracted to him by his energies and application as a young man. He was a hard and conscientious worker during his entire career, and was highly regarded by his Pennsylvania Railroad associates for his character and ability.

Mr. Miller spent his entire professional career, commencing in 1903, with the Pennsylvania Railroad Company. He passed through the grades of rodman, transitman, assistant supervisor (track), division engineer, and engineer of maintenance of way. He was assistant to the chief engineer, maintenance of way, Eastern Region, at Philadelphia at the time of his death. While occupying these positions Mr. Miller was engaged in a great variety of engineering work, which ranged all the way from simple surveys and design of small structures to the prosecution of reconnaissance surveys in the mountain territory of the Pennsylvania System; and design of such major structures as reservoirs, branch lines, plans for new freight yards, and changes in existing freight yards. Following this experience, Mr. Miller devoted his attention to maintenance of way work in which he demonstrated outstanding ability, and which resulted in his being advanced to the position of engineer of maintenance of way.

With the passage of the Valuation Law in 1913, he was called upon by the Pennsylvania Railroad Company to perform special duty in conjunction with the Federal Valuation Officers, which first involved field inventory of the property, and later the compilation of considerable cost data. His wide experience and knowledge was of considerable value, both to the railroad companies and the Bureau of Valuation. During the disastrous fire at the Broad Street Station, in Philadelphia, on June 11, 1923, he rendered valuable service of an emergency nature in restoring traffic at that terminal.

Mr. Miller, wherever located, always engaged in matters of civic interest, and made close contacts with engineering officers of the different communities. He was president of the Engineers' Society of Pennsylvania in 1932, and in November of that year he had the pleasure and honor of inducting President Herbert Hoover into the Engineers' Society of Pennsylvania at the White House in Washington, D. C., in the presence of more than one hundred engineers.

Mr. Miller died on December 18, 1939, at the age of fifty-nine at Ardmore, Pa.

Mr. Miller had two sons to whom he was devoted, and the interest he displayed in them reflected his own home training.

Mr. Miller was elected an Associate Member of the American Society of Civil Engineers on May 31, 1916.

ERI OLMSTEAD, Assoc. M. Am. Soc. C. E.[1]

Died April 13, 1939

Eri Olmstead was born in Portland, Mich., on October 12, 1885, the son of Allen and Elvira Olmstead. He received his early school training in that city and was graduated from the Portland High School in 1905. He entered the University of Michigan, at Ann Arbor, Mich., in 1907, and completed the civil engineering course in 1911.

Mr. Olmstead began his engineering career in July, 1911, as a surveyor and map maker for the Bermudez Company, a subsidiary of the General Asphalt Company, in Venezuela, South America. This temporary assignment was completed in December, 1911. He returned to the United States and accepted a position the following month with Stone and Webster Engineering Corporation of Boston, Mass. For the following two years he acted as draftsman, surveyor, and designer for many important undertakings which this company had in progress at that time. From 1914 to the middle of 1916 he acted in the capacity of chief checker for Stone and Webster on the new buildings which the Massachusetts Institute of Technology at Cambridge, Mass., was sponsoring at that time. Immediately thereafter he represented this firm as resident engineer on the construction of factory buildings for the Simplex Wire and Cable Company, and the Boston Woven Hose and Rubber Company. Leaving Stone and Webster in the fall of 1916, he accepted a position with the Harry M. Hope Engineering Corporation, also of Boston, as resident engineer in charge of construction of a complicated boiler house and pumping station for the Fisk Rubber Company, a power station for the Union Street Railway, at New Bedford, Mass., and a factory for the Schuhle Grape Juice Company at Highland, N. Y. This work occupied his complete time until February, 1920.

It was at this time that the C. B. Roberts Engineering Company of Boston had a contract calling for the construction of a refinery for the Louisiana Oil and Refining Company, at Shreveport, La., and Mr. Olmstead was appointed superintendent and engineer in charge of construction. This work was Mr. Olmstead's last assignment with eastern engineering firms.

Leaving Boston in the fall of 1921, he went to Detroit, Mich., and accepted the position of general superintendent of construction for the J. A. Utley Company of that city. He was with this company until the spring of 1925 and completed many fine factory buildings and residences of the better class.

In March, 1925, the general contracting firm of Beyster and Olmstead, Inc., was founded in Detroit with Mr. Olmstead as president. This contracting organization, although no longer existent, is well remembered among the construction fraternity in and around Detroit where most of their work was done.

In September, 1934, Mr. Olmstead accepted a position as resident engineer inspector with the Federal Emergency Administration of Public Works

---

[1] Memoir prepared by Milo F. Ohr, M. Am. Soc. C. E.

(PWA). In this capacity he represented the federal government on the complete waterworks projects at Port Hope, and Standish, and on the construction of the new elementary school building at Mount Pleasant, all in Michigan. Following this, his work covered the new hospital addition built for the City of Hamtramck, Mich., and the sewage disposal plant at Utica, Mich.

For more than three years preceding his death, Mr. Olmstead served as a traveling engineer inspector for the PWA within the State of Michigan. He visited construction jobs throughout the state, passing upon the work being done on the many projects, instructing and acquainting new engineer inspectors with their duties and responsibilities, and in general acting as a liaison man between the field and its construction problems and the office and its personnel. It was through this work in the latter part of his life that the helpfulness and cheerfulness ever present within this man was brought to so many people who enjoyed the opportunity to be associated with him. His passing will be a distinct loss to his many friends and associates, both within, and aside from, the business world.

He was married to Pearl Osborn on January 4, 1910, and is survived by his widow; his daughter, Barbara; and a sister, Mrs. George Erdman.

Mr. Olmstead was elected an Associate Member of the American Society of Civil Engineers on July 12, 1937.

VICTOR SMITH PERSONS, Assoc. M. Am. Soc. C. E.[1]

DIED MARCH 5, 1940

Victor Smith Persons, the son of the Rev. Greenleaf Elvero Persons, D.D. and Gertrude (Reed) Persons, was born on December 5, 1878, at Ashland, Ohio. His ancestors, on both sides, came from England and settled in New England early in the seventeenth century.

After completing his early school training, Mr. Persons entered Ohio Wesleyan University at Delaware, Ohio, in 1895, and was graduated with the degree of Bachelor of Arts in 1899. Later he attended Armour Institute of Technology at Chicago, Ill., and was graduated with the degree of Bachelor of Science in 1902. In this same year he was given the degree of Master of Arts at Ohio Wesleyan University. A few years later he served as instructor in Civil Engineering at Armour Institute and during this period he prepared for and received his Master's degree of Civil Engineering in 1907.

Immediately after graduation from Armour Institute he entered the employ of Noble and Modjeski, and for two years was connected with the construction of the Thebes bridge over the Mississippi River at Thebes, Ill., first as inspector, then as assistant engineer.

---

[1] Memoir prepared by C. B. Hopkins, Assoc. M. Am. Soc. C. E., and Otto G. Hintermann, Esq., Certified Architect, San Francisco, Calif.

In 1904 he joined the staff of the University of Chicago, Archæological and Research Department, and was detailed as engineer of excavation for the expedition in Mesopotamia and Egypt, remaining there for two years.

Upon his return to the United States he was employed by the City of Chicago as engineer on tunnel construction. He became interested in the then rapidly developing reinforced concrete industry and joined the staff of the Corrugated Bar Company of St. Louis, Mo., first as estimator, then as designer of all classes of reinforced concrete structures. Later he was sent to Portland, Ore., by the Concrete Steel Products Company of Chicago, there becoming their Pacific Coast representative in charge of design of reinforced concrete structures and the sale of steel reinforcing products.

In 1912 Mr. Persons settled in San Francisco, Calif., and continued his work in reinforced concrete design and development of steel reinforcing materials, his principal connection being with the L. A. Norris Company in the promotion and sale of Clinton Wire Cloth Company products. The development of many new uses for these products, and allied ones, was the result of his imagination and ingenuity.

From 1920 until his death Mr. Persons operated his own business, continuing his engineering design and doing his sales engineering work under the firm names of Persons, Dwan and Company and finally as The Persons Company. In his sales engineering work he represented, on the Pacific Coast, some of the outstanding national building specialty manufacturers.

Mr. Persons' career as a student, teacher, and engineer was marked by his devotion to the problem at hand, and by his conscientiousness and accuracy. In his business relationships he assumed a broad spirit of fairness and was above reproach in all his dealings. He was a bachelor, and is survived by a sister, Alice Lora Persons, and two brothers, C. E. and V. J. Persons. His recreations were simple and wholesome, and included bridge, golf, fishing, riding, and camping.

Mr. Persons was a member of Delta Tau Delta, social fraternity, and Phi Beta Kappa, scholastic honor society. He belonged to the Olympic Club, the Fraternity Club, the Producers Council, and the Mechanics Institute, all of San Francisco.

Mr. Persons was elected an Associate Member of the American Society of Civil Engineers on June 11, 1917.

CHARLES ARNER RUGGLES, Assoc. M. Am. Soc. C. E.[1]

DIED SEPTEMBER 6, 1938

Charles Arner Ruggles was born in Canfield, Ohio, on May 30, 1868, the son of Horace Greeley Ruggles, of Canfield, and Amanda C. (Hoyle) Ruggles, of Berlin, Ohio.

---

[1] Memoir prepared by E. W. Robinson, Assoc. M. Am. Soc. C. E.

The family is descended from John Ruggles of Nansing, Essex, England (the son of Thomas of Sudbury, Suffolk, England), who came to the United States with his wife, Barbara, and son, John, in the ship, *Hopewell,* and settled in Roxbury, Mass., in 1635.

Mr. Ruggles' great grandfather, Azor Ruggles, was born and brought up in Brookfield, Litchfield County, Conn. He was a millwright and went to Ohio on horseback in 1810 for the purpose of doing some work for Judge Canfield. After remaining a year he returned to Connecticut and in 1813 took his wife and six children to Ohio in two wagons and settled permanently in Canfield.

His grandfather, Charles, was a land surveyor and lawyer and his father was also a member of the Ohio bar. The latter served as a corporal in Company H, 105th, Ohio Volunteer Infantry, in the Civil War, and after practising law in Canfield for a number of years, moved to Wichita, Kans., with his family in 1874, where he was admitted to the Kansas bar and became a practising attorney.

Charles Arner Ruggles received his early education in the schools of Wichita, was graduated from Lewis Academy, and took an engineering course at Garfield University, at Wichita. On completion of his schooling, about 1890, he secured a position as architect and assistant engineer with a firm in Middlesboro, Ky., and was transferred from there to its office in Knoxville, Tenn. When a better opportunity was offered him by the Chicago Ornamental Iron Company in 1892, he joined their forces, remaining with them about three years, and becoming foreman draftsman.

From Chicago Mr. Ruggles came east, in 1895, and held positions as draftsman and designer with various ornamental iron works until 1897, when he became manager of the New York office of the Brown Ketcham Iron Works of Indianapolis, Ind., in charge of all work east of Pittsburgh, Pa.

He remained with the Brown Ketcham Iron Works for five years and in 1902 became manager of the New York office of the Columbian Fireproofing Company of Pittsburgh. In 1907 he was made manager of the New York office of Cramp and Company, of Philadelphia, Pa.

In 1910 Mr. Ruggles had an opportunity to go into business on his own account, in New York, N. Y., and he organized the firm of Ruggles-Robinson Company to do general contracting and building business. He became president of this firm, retaining the office until his death. During his last years he was not active in business, but devoted most of his time to the management of his personal and family affairs.

Mr. Ruggles was a man of modest and self-effacing character; he had few close friends and was always reticent about his personal activities and contributions to the well being of his fellowmen. On rare occasions he would unbosom himself and one might hear of his love for horses, as a boy in Kansas; of his escapades during vacation in Indian Territory; of his Militia service in the Tennessee National Guard; and of his membership in choral societies in Chicago. His one hobby in later life was his garden and orchard, to which he devoted much time, and where he raised specimen apples, mostly of the old-fashioned varieties. In his relations with clients and fellow workers, his ability and fairness in technical and business matters was outstanding.

Mr. Ruggles was married to Florence G. Clark on March 3, 1908, in New York City. He is survived by his widow, a daughter, Jean Campbell, and a brother, Rollin P. Ruggles.

At the time of his death he was a director of Charles and Company, a member of the Apawamis and Manursing Island clubs of Rye, N. Y., and, since 1903, a member of Albion Lodge No. 26, Free and Accepted Masons.

Mr. Ruggles was elected an Associate Member of the American Society of Civil Engineers on June 4, 1902.

HERMAN SCHNEIDER, Assoc. M. Am. Soc. C. E.[1]

Died March 28, 1939

Herman Schneider was born at Summit Hill, Pa., on September 12, 1872, the son of Anton and Sarah (Wintersteen) Schneider. At an early age he started to work as a breaker boy in the coal mines and, before entering college, he had worked as a helper on a construction gang and on survey parties.

He attended Lehigh University, at Bethlehem, Pa., from which he was graduated in 1894, with the Degree of Bachelor of Science in Architecture. In order to defray his expenses at college he worked in architectural offices during vacations and after school hours. His work was first as a blueprint boy and later, by time of graduation, as a designer. This practical work was extremely beneficial in helping him to utilize the theories taught in the classroom, and gave him a marked advantage at graduation over those students who had pursued academic work alone. This fact so impressed itself upon him that he never forgot it, and it was the idea born from this joint work and school program which influenced all the remainder of his life and led to the origin of cooperative education.

After graduation, Herman Schneider entered private practice as an architect in Cumberland, Md. During the three years that followed, he designed about three hundred buildings and superintended the construction of about seventy-five of them. In October of 1897, he accepted employment with the Oregon Short Line Railway, and from that time until June, 1898, he designed several hotels and depots for the railway. In June, 1898, he returned to South Bethlehem, Pa., where he worked as superintendent of construction for A. W. Leh, Architect.

During all of this experience, there was one thing that impressed itself upon young Schneider. That was the lack of practical knowledge shown by the young college graduates with whom he was associated. With the keen instinct of the scientist, he was already seeking a solution for this problem, and the answer seemed to him to be found in some combination of practice and theory, such as had been his own personal experience when he worked after school and on Saturdays in the architect's office at South Bethlehem, while attending Lehigh University. He decided to place this idea before qualified educational authorities and have it tried.

---

[1] Memoir prepared by a committee of the Cincinnati Local Section consisting of Raymond W. Renn, Assoc. M. Am. Soc. C. E., assisted by Prof. Clyde W. Park, Head of English Dept., Univ. of Cincinnati, Cincinnati, Ohio.

Hence he welcomed the opportunity of becoming connected with the faculty of his alma mater, and accepted an appointment as instructor in the Department of Civil Engineering in September, 1899. For four years, he continued as instructor at Lehigh, and during most of this time he actively sought the adoption of his idea of practical training to supplement the academic work at the university. The task of changing the educational system of an established engineering college was too much for a young instructor, however, and so in 1903, Schneider decided that the best procedure would be to carry his idea to a newer institution. The obvious fact that such an idea stood a better chance of success if applied in an industrial center, where the school and the shops existed side by side, became more evident.

So, in casting about for the best location for such a school, he found a vacancy existing in the University of Cincinnati, at Cincinnati, Ohio, and in 1903 he accepted an appointment as Professor of Civil Engineering at that institution. For three years he worked diligently, losing no chance to forward his idea of cooperative education. Finally, in 1906, the Board of Directors of the University of Cincinnati approved the adoption of the cooperative system as an experiment, the continuation of the approval to depend upon its success. At the same time, Professor Schneider was appointed Dean of the College of Engineering and was given full responsibility for the execution of his plan.

In September, 1906, the first class of cooperative students was formed under Dean Schneider's guidance. It consisted of 27 students in chemical, mechanical, and electrical engineering. As proof of the vigor and strength with which he attacked his problem, the biography of Herman Schneider, from this point, is largely the history of the cooperative system of education, and the history of the College of Engineering of the University of Cincinnati.

In 1911, the University of Pittsburgh, at Pittsburgh, Pa., conferred upon Dean Schneider the degree of Doctor of Science. From 1911 to 1913, he was a member of the Committee on School Inquiry of the City of New York. An important part of this work was the introduction of the cooperative plan in the New York, N. Y., high schools. Because of ill health, it was necessary for Dr. Schneider to terminate this work in 1915.

In September, 1917, Dr. Schneider accepted the appointment as Chief of the Industrial Service Section of the Ordnance Department, a new bureau which handled for the Ordnance Department all labor and employment matters relating to production in arsenals and private manufacturing plants. In this department he had to deal with labor problems which arose from handling contracts approximating $2,000,000,000 in connection with the procurement of material for the U. S. Army.

In February, 1918, he was chosen to represent engineering schools as a member of the advisory committee for the Committee on Education and Special Training. This Committee, appointed by the Secretary of War, was charged with the responsibility of training 90,000 men of the National Army for technical and skilled work of various kinds.

After the war, there followed a rapid succession of events in the educational and scientific development at the University of Cincinnati, for which Dr. Schneider was responsible. In 1919, cooperative courses in commerce were inaugurated, and the College of Engineering became the College of Engineering and Commerce. In 1920, organized research work was begun by the opening of the Leather Research Laboratory of the Tanners' Council of America, and the Institute of Scientific Research was established. In 1922 the School of Applied Arts was added to the cooperative group of the University by the introduction of a Department of Architecture. In succession were added the Departments of Landscape Architecture, Interior Decoration, Art Applied to Industry, and Ceramics. In 1924, a Resource Survey was begun which covered the territory within a radius of 300 miles of Cincinnati. In March, 1925, the Lithographic Research Laboratory was started, and in 1926 the Basic Science Research Laboratory which dealt with the combining and correlating of the natural sciences was established. During this era of development, all under the close personal supervision of Dr. Schneider, he became, in addition to the Dean of the College of Engineering and Commerce, the Director of the School of Applied Arts, the Director of the Institute of Scientific Research, and the Director of the Evening College.

In 1928, after much persuasion, Dr. Schneider transferred the seat of his activities from the Dean's Office in the Engineering College to the President's Office. Although he agreed to this change only upon the condition that he was to be relieved of the duties as soon as possible and returned to the activities in which he was most interested—scientific development and cooperative education—nevertheless he served as President of the University of Cincinnati from 1928 until 1932.

In 1931, Dr. Schneider and Prof. George Sperti announced the discovery of the method of irradiation of vitamin D by the application of selective ultraviolet rays, a discovery which has important bearing on increasing the nutritive and health building properties of foods.

The University of Cincinnati conferred the Degree of Doctor of Laws on Dr. Schneider in 1933 and made him President-Emeritus of the University. At the time of his death, Dr. Schneider headed the College of Engineering and Commerce, the Institute of Scientific Research, the School of Applied Arts, and the Evening College of the University of Cincinnati. In addition to these duties, he found time to serve with Charles F. Kettering, M. Am. Soc. C. E., President and Director of General Motors Research Corporation, as a consultant on the Walter P. Murphy Foundation, in the establishment of a new Institute of Technology at Northwestern University, at Evanston, Ill.

Although Dr. Schneider's life was essentially a life of action he still found time to do a great deal of writing. He was the author of "Arthur McQuaid, American," consisting of six short stories published in the *American Magazine*. Two of them were placed on the Honor Roll in Edward J. O'Brien's list of the best American short stories in 1917. Other works consisted of "Education and Industrial Peace," published in 1912; "Education for Industrial Workers," published in 1915; "The Problem of Vocational Guidance," May, 1938; essays and contributed editorials for the *Engineering News-Record* and the *Cooperative Engineer;* and numerous articles on educational subjects.

In 1931, the Cincinnati Institute of Fine Arts awarded Dr. Schneider the Sachs Prize for outstanding achievement during the year 1931 in the field of literature, art, and science. In 1936, he was awarded the Lamme medal by the Society for the Promotion of Engineering Education. He also served on the Advisory Council on Applied Physics of the American Institute of Physics in 1936.

Dr. Schneider was a member of the Society for the Promotion of Engineering Education; the Engineers' Club of Cincinnati; and the Commercial Club and Carbon Lodge No. 242, F. and A. M., of Mauch Chunk, Pa.

On July 27, 1904, Herman Schneider was married to Louise Bosworth at Cassopolis, Mich. They had no children. His widow survives him.

Dr. Schneider was a Presbyterian. A brief glimpse of his philosophy of life may be had from the following public statement:[3]

> "You can't go very far in modern science, groping toward an understanding of its absolutely perfect laws, without being forced—to your knees, I almost said—to the conviction that back of the whole scheme of things there is a most amazing Divine Intelligence.
>
> "Try to grasp some of the facts of astronomy and of astrophysics: of little patches of our sky containing hundreds of thousands of suns much greater than our own, of our galaxy of stars one hundred million light years across, and some billions of light years beyond, other galaxies and super-galaxies; then consider the solar systems which we call atoms—and let your mind run through the whole pulsating mystery of what we call 'matter' from the whirling electron to the super-galaxies, all held in a bewildering balance and movement by absolutely perfect law * * * well, if you grasp only a little of that, you just slough off your egocentric trends to personal acquisition of this and that, and try to get into the swing of the great movement of which you are a little part; and you strive to make your work conform. You get the feeling of infinite progress in accordance with a wonderful pattern which you can barely sense but which you can't understand."

Throughout an arduous and busy life, "Dean" Schneider, as he was always referred to by the students and by his associates, remained accessible to the least of them. Nothing gave the "Dean" more pleasure than to have a student come to his office and there, in quiet and privacy, pour out his troubles, and in turn listen to the timely and wise advice which Dean Schneider was able to give from the wealth of his research and experience.

The opening paragraph of the resolution adopted by the Cincinnati Section of the Society, upon his death, fitly pays tribute to his qualities:

> "Herman Schneider,—man, philosopher, dreamer, practical molder of lives and character, friend and counsellor of youth, confidant and arbiter in man's estate, has responded to the beckoning hand of The Infinite, whose might and wisdom were to his eyes so evident in the scheme of the universe."

Dr. Schneider was elected an Associate Member of the American Society of Civil Engineers on April 2, 1902.

---

[3] *Engineering News-Record,* June 10, 1926.

REGINALD CROWLEY SCOTT, Assoc. M. Am. Soc. C. E.[1]

DIED SEPTEMBER 30, 1939

Reginald Crowley Scott was born at Philadelphia, Pa., on September 23, 1892, the son of Valentine and Sara A. Scott. He was educated in the Philadelphia public schools and was graduated from the Central Manual Training High School. Later he attended evening classes in engineering subjects at Drexel Institute of Technology, at Philadelphia, from which he received a Certificate in the Collegiate Course in Engineering.

In June, 1910, he was employed as a rodman by J. H. Young, a civil engineer of Philadelphia. In October, 1911, he became a rodman and later a chainman with the Pennsylvania State Highway Department in the Philadelphia District, being subsequently transferred to the Bloomsburg District as a chainman.

Two years later Mr. Scott was employed by the City of Philadelphia in the Department of City Transit as a rodman. He advanced to the ranks of assistant engineer and junior assistant engineer. His work consisted of establishing lines, grades, and layouts necessary for the construction of the Frankford Elevated high-speed electric passenger line and for future transit routes.

In January, 1924, he was engaged by the Real Estate and Construction Company of Philadelphia as managing engineer on general construction work.

He returned to service in the Department of City Transit, in June, 1924, advancing in June, 1936, to the rank of senior assistant engineer, which rank he held until his death. As assistant to the division engineer he was responsible for the supervision of lines, grades, estimates, records, and construction of portions of the Broad Street, Ridge Avenue-Eighth Street, Locust Street and South Broad Street subways and appurtenant work.

Mr. Scott's career in the engineering profession was notable because of his strict attention to details of his work, careful study of construction problems, loyalty to his employer and associates, and a broad spirit of fairness to all who through business came in contact with him. He possessed a fine character and a splendid personality.

He took an active interest in the work of the Philadelphia Section, having been elected to the office of Secretary-Treasurer, which office he held at the time of his death. He was a Founder Member of the Pennsylvania Chapter of the American Society of Professional Engineers.

On August 25, 1926, Mr. Scott was married to Alice A. Newis, who survives him. Also surviving are his mother, his sister Emma, and a brother Howard.

Mr. Scott was elected an Associate Member of the American Society of Civil Engineers on October 11, 1920.

---

[1] Memoir prepared by Charles H. Stevens, M. Am. Soc. C. E., aided by Charles S. Shaughnessy and Howard S. Hipwell, Members, Am. Soc. C. E.

ALEXANDER JENIFER TAYLOR, Assoc. M. Am. Soc. C. E.[1]

DIED FEBRUARY 27, 1940

Alexander Jenifer Taylor was born in the town of Dover, Del., on February 9, 1875, the son of Alexander J. and Wilhelmina (Baynard) Taylor. His early education was received in the private and public schools of his home town. In 1889 he entered Delaware College (later the University of Delaware), at Newark, Del., and was one of the thirteen who graduated four years later, being valedictorian of his class and the youngest in his class to receive a degree.

After his graduation Mr. Taylor began work as a rodman with the Park Department of the City of Wilmington, and a year later became the assistant engineer of the Street and Sewer Department in charge of the drafting room, surveying, and field work.

At the outbreak of the Spanish-American War, Mr. Taylor joined the Delaware volunteers and became Captain of Company "M," Sixth Regiment. At the close of the war, he resumed his engineering studies at Massachusetts Institute of Technology, at Boston, Mass., graduating in 1901 with a Bachelor of Science degree.

He returned to Wilmington, but soon became interested in the possibilities of sulfur deposits in Alaska. He joined a group of engineers to make a survey there and acted as assistant to the engineer in charge of that survey. Due to financial difficulties the group returned to Wilmington after five months in Alaska. Mr. Taylor immediately resumed his engineering work with the Street and Sewer Department. From September, 1902, to December, 1903, he was with the late T. Chalkley Hatton, M. Am. Soc. C. E., consultant engineer, as assistant engineer on design of water and sewerage systems for several towns, having had charge of construction of water works in Hammonton, N. J., and Matawan, N. J.; street paving in Frederick, Md.; and Price's Run Sewer, in Wilmington (a $100,000 project). From December, 1903, to September, 1906, Mr. Taylor was engineer and superintendent for park commissioners, in Wilmington, in charge of maintenance work and of designing and constructing driveways, paths, swimming pools, and bath houses.

In 1910 he was appointed city engineer for Wilmington, which position he retained until 1915 when he entered the employ of E. I. du Pont de Nemours and Company. His engineering ability and executive ability were soon recognized by the du Pont Company, and he was placed in charge of construction of the Kennett Highway, one of the early reinforced concrete roads in the state, improved by P. S. du Pont. He acted as assistant engineer and as resident engineer at Williamsburg, Va. (Penniman plant), and as resident engineer at Gibbstown, N. J. (Repauno plant), and Arlington, N. J., in charge of construction work on industrial plants. At this time, Mr. du Pont was looking for a capable man to help administer the state-wide important school building program planned for Delaware. That post was filled by Mr. Taylor, who entered into the work with much zeal and a desire to establish a project that would forever be a monument in the State of Delaware.

---

[1] Memoir prepared by J. L. Warner, M. Am. Soc. C. E.

Although Mr. Taylor's life work was varied, his principal contribution to his state was his keen interest in the construction of public schools throughout Delaware during the period when the school building program was being improved by the Delaware School Foundation and Delaware School Auxiliary. Mr. Taylor's thorough knowledge of civil engineering and his experience in this branch of the work established him as an outstanding authority on school building. He became vice-president and chief engineer of the Delaware School Auxiliary which was linked with the Service Citizens Association of Delaware. In 1927, when the Service Citizens went into history, the Delaware School Auxiliary continued under the name of the Delaware School Foundation; and upon the death of its president, Joseph H. Odell, in 1929, Mr. Taylor became the president. He continued as chief engineer, although the major work of the Foundation had been completed.

As an alumnus of the University of Delaware, with degrees of Bachelor of Science in Civil Engineering and Civil Engineer, he was one of its most active members. His keen interest and open enthusiasm in all activities and his readiness to promote all worthy projects will always be remembered by his associates and those interested in the educational work of Delaware. The well-equipped gymnasium at the university was named in his honor, and he was serving as a trustee of the university at the time of his death.

It was the custom of Alexander J. Taylor to devote himself energetically to each task which fell to his lot. His keen interest continued until each job was done, and done satisfactorily. He was a capable engineer who served well both public and private interests during his entire career.

As president of the Delaware School Foundation, Mr. Taylor's name will go down in Delaware History as the able director of the program of that organization for modernizing the state's public schools. This undertaking, financed by Pierre S. du Pont, resulted in the construction of fine new schools in all parts of the state. As a citizen, Mr. Taylor was respected and appreciated by his fellow citizens. He was a willing, cheerful, and helpful participant in those public undertakings that seemed to him to be in the interest of the general good.

It was without hesitancy that, with this record of reliability and competency, he was appointed executive secretary to the Delaware Liquor Commissioner after the repeal of prohibition. Although Mr. Taylor neither drank nor smoked, he entered into his new duties with close attention and sincerity in guiding the state out of prohibition. Where he had once moved in architectural and engineering circles, Mr. Taylor, as the liquor commissioner's secretary, found himself in almost a new world, but he quickly became respected and admired by all with whom he came in contact in this new and strange work for his fairness and intelligent grasp of the problems. In 1938 his health became impaired, but he continued in his position as executive secretary to the liquor commissioner. His sudden death, despite the fact that his health had not been perfect, came as a shock to the citizens of Wilmington. His dealings with the citizens of his state leave with them a knowledge of Alexander Taylor as a man who was never unwilling to try to solve any problem; and in his engineering career his sound and unerring judgment in engineering matters, especially in the State of Delaware's public schools, stands out as the excellent work in engineering of Alexander Taylor.

Mr. Taylor was married to Isabelle Macallister, on January 7, 1902. His wife, a son, Alexander J., and a daughter, Eleanor (Mrs. L. Samuel Vadner), survive him.

Mr. Taylor, a Thirty-Second Degree Mason, was a member of the Masonic Club of Delaware, a member of the Shrine, past-president of the Knights of the Round Table, and a member of the Engineers Club of Philadelphia.

Alexander J. Taylor was elected a Junior of the American Society of Civil Engineers on October 3, 1899, and an Associate Member on April 3, 1907.

GEORGE COPELAND URQUHART, Assoc. M. Am. Soc. C. E.[1]

Died January 10, 1939

George Copeland Urquhart, the son of Capt. Moses Johnston and Susan (Copeland) Urquhart, was born at Steubenville, Jefferson County, Ohio, on Saturday, March 24, 1866. His family moved to Mansfield, Ohio, in 1873, and to Mount Vernon, Ohio, in 1875, returning to Steubenville in 1877. Mr. Urquhart received his early education in Miss Brown's Private School at Steubenville and the public schools at Mansfield and Mount Vernon. He completed his education at Steubenville, graduating from Steubenville High School in June, 1883.

Mr. Urquhart's first experience on engineering work was during his school vacation in 1882, when he was employed on the engineering force of the Maintenance of Way Department of the Pittsburgh, Cincinnati, and St. Louis Railway Company. Upon graduation the next year he was appointed to the engineering force of the Cincinnati and Muskingum Valley Railway Company, with headquarters at Zanesville, Ohio. In 1884 he was transferred to the Pittsburgh, Cincinnati, and St. Louis Railway Company with office at Pittsburgh, Pa.; and on July 5, 1886, he was promoted to Assistant Engineer. In addition to railroad work during this time he conducted the surveys in connection with the erection of a water-works system for the villages of Dennison and Uhrichsville, Ohio.

On April 20, 1888, he was appointed Assistant Engineer in Charge of new construction, with headquarters at Steubenville. His work included double tracking 12 miles of the Panhandle Division of the Pittsburgh, Cincinnati and St. Louis Railway between Bulger and Colliers, W. Va., the completion of Dinsmore Tunnel for double track, and the widening of the bridge over the Ohio River at Steubenville for double track.

---

[1] Memoir prepared by a Committee consisting of L. J. Riegler, M. Am. Soc. C. E., Paul J. Urquhart, Aluminum Co. of America, and James L. Mason and A. R. Meredith, Pennsylvania Railroad Co., Pittsburgh, Pa.

In 1890 he moved his headquarters to Bowerstown, Ohio, and supervised the widening of tunnel No. 10 and the construction of double track from Philadelphia Road to Bowerston (6 miles). This work included street paving, sewering, and municipal improvements in the village of Dennison. In 1893 he was appointed Assistant Engineer in the office of the Chief Engineer of the Pittsburgh, Cincinnati, and St. Louis Railway, in charge of tax and real estate matters.

On April 1, 1899, the Real Estate Department of the Pennsylvania Lines West of Pittsburgh was organized and Mr. Urquhart was appointed Assistant Real Estate Agent for the Southwest System, Mr. Charles D. Law being the head of the entire department. On January 1, 1903, Mr. Urquhart was appointed Real Estate Agent of the Lines West succeeding Mr. Law who died in November, 1902. On March 1, 1920, the organization of the Pennsylvania Railroad Company was changed into a Regional System and Mr. Urquhart was appointed Real Estate Agent for the Central Region. By reason of further reorganization of the System he was appointed Assistant to General Real Estate Agent on February 1, 1923, and on July 1, 1924, General Agent, Real Estate Department, both positions with headquarters at Pittsburgh.

While head of the Real Estate Department of the Pennsylvania Lines West of Pittsburgh and its subsidiary corporations, Mr. Urquhart was in full charge of the departmental activities covering consultation upon land survey work, and other engineering related thereto, in connection with acquisition and administration of land. Upon assuming office in 1903, he was confronted with the largest program of new construction work that the railroad had ever undertaken, including many new lines in Pennsylvania, Ohio, Indiana, and Illinois, double tracking of a large part of the entire system, the construction of many yards and terminals, and track elevation in the larger cities of the Lines West of Pittsburgh.

During the earlier period, while in charge of construction projects, particularly the double tracking of the Ohio River bridge at Steubenville, and the widening of the tunnels (all of which had to be done along with the maintenance of an exacting main line railroad traffic) he earned a reputation of great dependability and reliability and won the confidence of the railroad's operating officers. To his later duties he brought a wealth of knowledge and skill in analyzing and solving intricate title and boundary problems involved in the purchase and administration of real estate on a large scale, and under many diversified conditions. He was considered an expert on land values and on taxation. Mr. Urquhart retired from active service of the Pennsylvania Railroad Company under its pension regulations on January 31, 1932.

He was married on September 3, 1896, to Mrs. Alberta V. Thompson (née Alberta V. Mills) who died May 22, 1913. On April 11, 1916, he was married to Mary Anna McCombs, who survives him.

Mr. Urquhart was a member of Dallas Lodge No. 508, F. and A. M.; Pennsylvania Consistory, A. A. S. R.; and Syria Temple, A. A. O. N. M. S. He was a member of Christ Methodist Episcopal Church and served on its Board of Trustees; for some years he was its Secretary, and was a member of the Board at the time of his death. He was a member of the Engineers Society of Western Pennsylvania from 1893.

To those who knew him best he was a kindly man of great personal charm and of the most lovable characteristics. He was regarded by all who knew him as an able and conscientious worker and a delightful friend. He was a man of clear vision and of the staunchest integrity.

Mr. Urquhart was elected an Associate Member of the American Society of Civil Engineers on May 6, 1891.

HAROLD EMIL VON BERGEN, Assoc. M. Am. Soc. C. E.[1]

DIED FEBRUARY 28, 1940

Harold Emil von Bergen was born in Petersburg, Nebr., on July 7, 1904, the son of J. F. and Anna (Schultz) von Bergen.

He received his elementary and high school education in the public schools of Nebraska. After graduation from high school, in 1924, he went to California and worked for a year in pipe-line maintenance with the Pacific Gasoline Company in Taft. In 1925, Mr. von Bergen entered Oregon State College, at Corvallis, Ore., and was graduated in the class of 1929, with the degree of Bachelor of Science in Civil Engineering. He was affiliated with Theta Chi social fraternity in college.

While attending college, he worked each summer with the City of Klamath Falls and the California-Oregon Power Company in Oregon and the Iowa-Nebraska Power Company in Nebraska in order to gain experience in surveying and construction. After graduation from Oregon State College, he was employed for nine months by the Reclamation Commission of the State of Oregon on drafting and dam analysis.

Mr. von Bergen returned to California in March, 1930, and accepted a position as junior engineer of hydraulic structure design with the Division of Water Resources, Department of Public Works, State of California, in connection with the administration of the "Act Governing the Supervision of Dams," enacted in 1929.

He left the Division of Water Resources in July, 1933, and took a position with the U. S. Forest Service at Quincy, Calif., as chief of a surveying party. He returned to the Division of Water Resources in March, 1935, as water master on the Pit River stream system.

Mr. von Bergen was particularly well qualified to make involved structural and hydraulic analyses, as he possessed an outstanding and rare power of independent and logical thinking. He was the author or co-author of several papers[2, 3] and discussions[4, 5] which have appeared in Society publications.

---

[1] Memoir prepared by a Committee of the Sacramento Section consisting of Gordon Zander, M. Am. Soc. C. E., Chairman, and T. R. Simpson and I. M. Nelidov, Assoc. Members, Am. Soc. C. E.

His geniality, personal charm, and outstanding ability as a pianist made him an indispensable participator in the programs of the Rotary Club at Alturas, Calif.; the Sacramento (Calif.) Section of the Society; and other musical and theatrical events in Sacramento. He was a man of strong physique and gloried in the outdoor functions of his work. His untimely and accidental death by drowning occurred in the line of duty when a boat, from which he was making a measurement of emergency flood flow in the Sacramento by-pass, capsized.

Mr. von Bergen was married in Reno, Nev., on April 1, 1934, to Frances Evelyn Rooney of Sacramento. He is survived by his widow and his daughter, Della Ann von Bergen; his mother, Anna S. von Bergen; five sisters, Alice, Katherine (Mrs. Albert Ohlman), Grace (Mrs. Otto Jensen), Elizabeth (Mrs. True Phillips), and Clara (Mrs. Ed Meyers); and two brothers, Arthur and Max.

Mr. von Bergen was elected a Junior of the American Society of Civil Engineers on July 14, 1930, and an Associate Member on December 14, 1936.

RALPH WATTS WARDWELL, Assoc. M. Am. Soc. C. E.[1]

Died June 28, 1939

Ralph Watts Wardwell was born in San Francisco, Calif., on February 26, 1879, the son of Atwater Murdock and Louise (Watts) Wardwell. He was educated in the public schools of Berkeley, Calif., and the University of California, in the same city, where he pursued a course in Civil Engineering. During his school years he took an energetic part in all activities, and was a member of Delta Upsilon fraternity.

His first professional work was as assistant engineer, U. S. Reclamation Service, on the Truckee-Carson Project in Nevada, and the Klamath Project in Oregon. This work included the location and construction of irrigation and drainage canals with accompanying tunnels, diversion dams, and headworks, and covered the period from July, 1904, to January, 1908. Through June of the latter year he was instrumentman and dredge inspector for the Southern Pacific Railroad Company on construction work in the vicinity of San Francisco Bay. Then followed a year as assistant engineer with Viele, Blackwell and Buck, building a timber rock-filled dam on the North Fork of the Feather River for the Great Western Power Company, and preparing maps, plans, and

[1] Memoir prepared by N. R. McKay, Birmingham, Ala.

estimates for a proposed power development on the North Slope of Pikes Peak in Colorado.

Mr. Wardwell's work for the Power Company attracted the attention of the Colorado Springs Heat, Light and Power Company, a public utility serving the cities of Colorado Springs, Colorado City, and Manitou, Colo., with electricity, gas, and steam heat, and in April, 1909, he accepted the position of assistant superintendent. Soon he was advanced to chief engineer, which position he held until March, 1914, when he resigned to become chief engineer in charge of the Geological Department and Water Supply System for the Fuel Oil Department of the Atchison, Topeka and Santa Fe Railway Company.

In May, 1917, he left the railway company to become chief engineer of the Western Water Company of Taft, Calif., and in October of the same year he was made general manager. This company served industrial and domestic consumers in the Midway-Sunset Oil Fields, Kern County, California.

Meanwhile, the United States entered the World War, and the call for capable engineer officers became more and more insistent; so in October, 1918, Mr. Wardwell was commissioned a Captain in the U. S. Engineers. He trained at Camp Humphreys, Virginia (later known as Ft. Belvoir), and for a time was detailed on special duty with the Coast Artillery. Receiving his honorable discharge in October, 1919, he was employed by the Bureau of Internal Revenue in the Oil and Gas Valuation Section. He was valuation engineer until August, 1921, and was then advanced to the office of Chief of California and Foreign Sub-Section. This work consisted of the estimation of oil and gas reserves, and the appraisal of oil and gas producing properties for income tax purposes. In February, 1923, he left the Bureau and became consulting engineer for a group of clients in the presentation and handling of engineering matters before the various government departments.

In February, 1926, Mr. Wardwell moved to Florida where he spent twelve years, the time divided between various engineering enterprises and fruit growing. As superintendent of the Coral Gables Construction Company he was engaged in the design and construction of the water and electric systems of that community and later as local manager for the Florida Power and Light Company. The years from 1931 to April, 1936, were spent in the employ of the U. S. Engineers, War Department, as civilian engineer on the Caloosahatchee River, Lake Okeechobee Drainage Project. In March, 1938, he was called to assist in the survey of the Passaic River Watershed. He took charge of the section on flood damage and reservoir valuations and organized the work of compiling data and collecting hydrologic data. This was his last work. Returning to his home in Providence, R. I., on the evening of June 27, 1939, he was taken ill and died very suddenly soon after midnight. His body was cremated and the ashes buried in Arlington National Cemetery, Virginia.

He is survived by his widow, the former Ruth Letitia Halpenny of Washington, D. C., and three children by a former marriage, Ralph Watts Wardwell, Jr., Robert S. Wardwell, and Louise Wardwell Spence.

Outside his professional activities, Mr. Wardwell experimented with candid camera photography; golf was his diversion; and during his years in Florida he was particularly interested in, and devoted time and attention to, Sea Scouting for boys.

Ralph Watts Wardwell was one of the vast army of engineers who never experience wide recognition—those who work with no idea of display, yet leave their mark on each structure they build. Drawing from a wide experience with fundamentals, Mr. Wardwell solved the problems he encountered by careful, thorough analysis, and the application of sound engineering principles—no ostentation, but persevering, diligent efficiency. One of a team, sometimes the leader, sometimes a wheel horse, he always pulled his share of the load—appreciated and respected by his fellows.

Mr. Wardwell was elected an Associate Member of the American Society of Civil Engineers on May 6, 1914.

WILLIAM TIBBITTS WEBB, Assoc. M. Am. Soc. C. E.[1]

DIED JUNE 13, 1939

William Tibbitts Webb was born in Cambridge, Mass., on August 13, 1879. He was the son of William W. and Emeline D. Webb, and obtained his early education in Providence, R. I. From 1898 to 1899, he was a special student at Brown University, in Providence, and later took special extension courses at Columbia University in New York, N. Y., in 1909 and 1910.

From August, 1896, to 1902 he was a student engineer, transitman, and inspector in the office of the city engineer at Providence. In December, 1902, he accepted a position as transitman on location on the Norfolk and Western Railway in Virginia and West Virginia, and remained at this work until October, 1903. From September, 1904, to December, 1905, he was chief inspector in charge of masonry work on the new sewerage system and treatment plant for the town of Dansville, N. Y., leaving this work to go with Westinghouse, Church, Kerr Company, on the construction of the Pennsylvania Terminal in New York. He worked here for some months as inspector, and, until December, 1907, as chief of field party. In this latter capacity he was in charge of the excavation, foundations, and steel erection for the Eighth Avenue Viaduct, and of the location and erection of the power plant, reinforced concrete tunnels, and a drainage system.

On completion of the work on the terminal, he entered the Civilian Engineering Department of the U. S. Army. From January, 1908, until May, 1911, he was engaged as a civil engineer and draftsman at the U. S. Military Academy at West Point, N. Y., where he made the necessary topographical surveys and maps for the location of new buildings, highways, and retaining walls, and also designed a new drainage and sewerage system for the north end of the academy. The remainder of his time on this assignment was occupied as structural engineer on foundations, design, and checking of steel and reinforced concrete construction of the chapel, gymnasium, guard house, and riding hall.

---

[1] Memoir prepared by James M. Bell, M. Am. Soc. C. E.

In May, 1911, he was appointed engineer to the quartermaster at West Point, and in this capacity had charge of all surveys and engineering in connection with the enlargement of the Academy. This included the new East Academic Building constructed at that time.

On completion of this work, in May, 1913, and until the end of that year, he was again with the Corps of Engineers of the U. S. Army, principally engaged in specifications and similar work. Toward the latter part of 1913 he was sent to San Juan, Puerto Rico, for the Army Engineers. There he made a survey for the establishment of pierhead lines and extensive dredging work. He also completed an inspection of other Puerto Rican harbors and had the supervision of the removal of certain wrecks along the coast.

In March, 1916, he left the Army Engineering Corps to go to J. G. White and Company as engineer on the installation of a water supply and distribution system for the cities of Remedios and Caibarién, Cuba. This work completed in September, 1916, he took a position with the West Indian Sugar Finance Corporation in charge of the erection of a large sugar mill at Alto Cedro, Cuba. This work was completed in March, 1917, and until January, 1918, Mr. Webb remained with the same company as resident engineer at San Pedro de Macorís, Dominican Republic. Here he built considerable railway extensions and was in charge of the maintenance of all railroads and structures of this group; also, he acted as consulting engineer for the City of San Pedro de Macorís in the extension of their drainage and sewerage system.

From January, 1918, to May, 1918, Mr. Webb was with the Public Works Department of the Dominican Republic as designing engineer, and in this capacity he designed a reinforced concrete dock for San Pedro de Macorís and four large reinforced concrete bridges for the 130-mile main highway across the island.

In July, 1918, he returned to the United States and entered the Army with the rank of Captain—Quartermaster's Corps. He worked in the Construction Department as cost engineer on the construction of a picric acid plant at Brunswick, Ga. While in this post he had considerable incidental work in connection with the design and layout of railroad, telephone, drainage, and water supply systems, the latter part of his time being principally occupied in the disposal of salvage material after the Armistice.

On giving up his commission, he was transferred to the Reserve Corps, and in July, 1919, went to Brazil, where he spent the remainder of his life. Here he was first engaged as representative for Livermore, Rojas Company, exporters, New York, in developing an organization for the sale of railroad construction machinery and supplies.

From August, 1922, to February, 1927, he was manufacturing agent for many manufacturers of machinery and construction equipment—principally, Koehring Mixers, C. L. Best Tractors, Russel Road Machinery, International Trucks, Magor Car Corporation, and Dupont Explosives. The latter representation occupied most of his time, as up to that date all explosives were imported and the representative of these firms was of necessity in constant contact with all of the major construction work done in the country.

In February, 1927, Mr. Webb gave up his representations of these manufacturers, and took a position as purchasing agent for the Emprezas Electricas Brasileiras, the Brazilian Subsidiary of the American and Foreign Power Company who, in the latter part of 1926, began to purchase many electrical operating properties in Brazil and shortly expanded until they owned public service operating properties in almost every state of the country. In March, 1929, Mr. Webb was put in charge of the Land Title Investigation of the same organization, a position which he occupied until his resignation in 1931.

From that date until his death, Mr. Webb was principally occupied in enterprises of interest to the American Colony of Rio de Janeiro, Brazil. He was a charter member of the Gavea Golf and Country Club, and was to no small degree responsible for the successful development and expansion of that enterprise. He was an ardent golfer and to the day of his death was one of the most regular patrons of the club, his broad engineering knowledge and experience having been freely utilized by the club on many occasions in working out their problems in connection with roads, water supply, etc., not to mention the preparation and maintenance of the course itself.

He was also always interested in educational matters and was very helpful in the consultations and work which have been done for the establishment of an American school in the community. He was a member of the Rio de Janeiro American Chamber of Commerce, and for several years was a director of it.

In 1922 he became a member of the committee headed by D. C. Collier, U. S. Commissioner to the Brazilian Centenary Exposition in Rio de Janeiro in 1922.

Mr. Webb was married on April 6, 1910, to Mary Washbun Murtha of New York, who survives him. There were no children, and his only other surviving relatives are two nieces, Mrs. Allan H. Chalmers, wife of the Rector of the Broadway Tabernacle Church, New York, and Mrs. Dudley Shannon Mackenzie, of Washington, D. C.

Mr. Webb was highly esteemed by all those who had personal contact with him, and his integrity and fairness in business dealings made him particularly admired. His death from acute indigestion in June of this year came as a great shock to all of his friends.

Mr. Webb was elected an Associate Member of the American Society of Civil Engineers on May 7, 1913.

NATHAN DAVIS WHITMAN, Assoc. M. Am. Soc. C. E.[1]

DIED SEPTEMBER 29, 1939

Nathan Davis Whitman was born in Boston, Mass., on March 23, 1878, the son of Nathan Davis Whitman and Helen (Mitchell) Orr. His paternal ancestry is coincident with the staunch history of New England and dates back to John Whitman, one of the earliest settlers in Weymouth, Mass. (1638). The Orr family, too, was prominent in New England, having established the first triphammer shop in the area, which shop supplied many cannons and muskets to the American forces in the Revolutionary War.

---

[1] Memoir prepared by Ernest F. Bent, Esq., Am. Concrete and Steel Pipe Co., Los Angeles, Calif.

Mr. Whitman was educated in the public schools of Boston. He then attended the Massachusetts Institute of Technology, at Cambridge, Mass., for one year, transferring at that time to the Massachusetts State College at Amherst, Mass. He received a degree of Bachelor of Science from the latter college in 1901. During this period, he spent his summers as draftsman in various offices in Boston and was an instructor in drawing at college.

After graduation, Mr. Whitman was employed by George S. Pierson, M. Am. Soc. C. E., consulting engineer of Kalamazoo, Mich., becoming his assistant engineer. His experience in this office was varied and formed an excellent background for all his subsequent work. Here he worked on the layout and design of sewer systems, water supply developments, substructure design and construction for bridges, and sewage disposal plants. After finishing the sewage disposal plant for Jackson, Mich., he left Mr. Pierson in 1905 to become engineer for the Reinforced Concrete Pipe Company of Michigan, at Jackson.

The reinforced-concrete pipe industry in the United States was then in the formative period and furnished Mr. Whitman an opportunity to grow with, and contribute to, a new field. To this end, he was more than successful, attaining an unquestioned national position as an engineering authority on concrete pipe. He developed several types of joints, improvements in form design, methods of reinforcing, and numerous machines and devices essential to the manufacture of pipe. His study and analyses of the problems of pipe production contributed much to the achievement of high quality pipe which is standard today.

In 1907 Mr. Whitman was transferred to Los Angeles, Calif., where the Reinforced Concrete Pipe Company of Los Angeles was formed, and for this company, as engineer, he was in charge of all engineering and design of reinforced-concrete pipe manufactured for water-pressure lines, sewers, and drains.

In 1913, Mr. Whitman returned to the East to continue his work with the Reinforced Concrete Pipe Company of Chicago, Ill., which company he served as secretary, director, and engineer until 1919.

For the next several years, Mr. Whitman left professional engineering to engage in sales work in San Francisco, Calif., and northern California where he conducted his own business.

In 1923 he returned to his chosen work in the concrete pipe industry, becoming chief engineer for the Bent Concrete Pipe Company in Los Angeles. He retained this position when this company merged with the Western Concrete Pipe Company to form the American Concrete and Steel Pipe Company, and was active until a short time before his death. During this period he supervised the design and construction of many large pipe lines in the Western States for water supply, irrigation, and sanitation.

In 1927, his company was the first in the United States to use, on a large commercial basis, the centrifugal process for the manufacture of reinforced-concrete pipe. The advantages of this superior pipe for water-pressure lines became apparent at once, and in the many developments necessary, Mr. Whitman's skill and knowledge as a pipe engineer played an important part in the design, construction, and successful performance of many such lines. Among these were a 30-mile domestic water supply line for Phoenix, Ariz., in 1931, and important lines for the California Water Service Company in the San Francisco Bay area in 1929, and for the La Mesa, Lemon Grove and Spring Valley Irrigation District near San Diego, Calif., in 1934.

Later his company undertook the manufacture of cylindrical reinforced-concrete pipe for pressure lines of high head and large diameter. Here again Mr. Whitman's abilities as the company's chief engineer were indispensable in the intricate problems of the design of such structures, which involve pressure, surge, contraction and expansion, load bearing, thrust, etc. Notable among these lines were 5 miles of 62-in. pipe (operating head 400 ft) for the Hetch Hetchy Water Supply for San Francisco in 1934, and several sections aggregating 15 miles for the City of Tacoma, Wash., from 1934 to 1939. Mr. Whitman's ability, experience, and contribution culminated in his cooperation with the designing engineers of the Metropolitan Water District of Southern California in the manufacture and installation in 1937 of 17 miles of 12-ft 8-in. and 11-ft 8-in. diameter reinforced-concrete pipe (heads to 230 ft) for the Colorado River Aqueduct, this being the largest pipe line of its kind constructed to that date.

So outstanding had Mr. Whitman's integrity, experience, and engineering ability become through these many years in this industry that often he was called in by consulting and public body engineers as an expert for their designs and to make recommendations.

Mr. Whitman was regarded with esteem and affection by his office colleagues, plant superintendents, foremen, and shop workers. His quiet humor, his wealth of general knowledge, and his friendly personality endeared him to all with whom he came in contact. His work was his hobby and he kept abreast, if not ahead, of the progress made in the pipe industry and engineering; nor did the fact that he had chosen a special field of engineering limit his viewpoint for he maintained an active interest in and had a profound knowledge of all engineering.

Mr. Whitman was married to Rose Marie Dickert of Milwaukee, Wis., on May 7, 1908, in Los Angeles. He is survived by his widow; a son, Nathan Davis Whitman, Jr., Assoc. M. Am. Soc. C. E.; and a grandson, Nathan Davis Whitman, IV.

Mr. Whitman was elected an Associate Member of the American Society of Civil Engineers on December 5, 1906.

JOHN THAD WHITNEY, Assoc. M. Am. Soc. C. E.[1]

DIED SEPTEMBER 30, 1938

John Thad Whitney was born on September 13, 1891, at Granville, Vt. He was the only child of Horace Harvey Whitney, who was descended from the early English settlers of New England, and Louise (Kerr) Whitney, whose Irish ancestors came to the United States in 1852.

His father, who was a merchant, operated a general country store at Northfield Falls, Vt. Both of John's parents had the outstanding qualities of sterling character, lovable personality and excellent judgment, and were virtually bulwarks of stability in their community.

Young John was reared in Northfield, Vt., where he received his elementary and high school education, graduating in 1909. During his early years, the excellent environment of clean living, honesty, and religious affiliation afforded him by his parents and New England tradition were to have a great effect on shaping his life.

He was graduated from Norwich University, at Northfield, with the degree of Bachelor of Science in Civil Engineering in June, 1913. Norwich University is a State-endowed military school and at the time that John Whitney attended, the students, in so far as military training was concerned, were members of the First Cavalry, Vermont National Guard. Throughout his life he maintained a sincere interest in his University. In later years he completed three graduate courses in advanced mechanics and mathematics at Carnegie Institute of Technology at Pittsburgh, Pa. At the time of his death he had nearly completed two theses for graduate degrees at Norwich University as follows: "The Transmission of Vertical Pressures Through Earth" and "Correlation Between Less-Than-One-Day Rainfalls and One-Day Rainfalls in the Upper Ohio River Basin."

In August, 1913, Mr. Whitney became connected with the U. S. War Department and served for two years as Inspector on the construction of Ohio River locks and dams in the Wheeling, W. Va., Engineer District. This was followed by two years as Field Engineer with the H. Koppers Company, of Pittsburgh, on the construction of a by-product coke plant at Follansbee, W. Va.

In September, 1917, Mr. Whitney entered the Officers' Training Camp, Fort Benjamin Harrison, Indiana. He was commissioned Second Lieutenant, Field Artillery, O. R. C., on November 27, 1917, and assigned to the 89th Division. He served as a member of the American Expeditionary Forces from July 10, 1918, to July 6, 1919. During this period he was engaged principally in the transportation of artillery supplies in connection with the 2d Corps Artillery Park and participated in five major offensives as follows: Aisne Marne, St. Mihiel, Oise-Aisne, Meuse-Argonne, and Vesle-Sector. He was discharged on July 11, 1919, at Camp Dix, New Jersey, as a Second Lieutenant, Field Artillery.

---

[1] Memoir prepared by a Committee of the Pittsburgh Section consisting of Harry A. Hickman, M. Am. Soc. C. E., and Ely G. Fenton, Assoc. M. Am. Soc. C. E.

Upon return to civil life Mr. Whitney was connected with the Vermont State Engineer Department (later combined with the State Highway Department) as Assistant Engineer. In this connection, he served successively as Inspector and Resident Engineer on highway construction, in charge of bridge design, and as Assistant to the State Engineer. During the last nine months of this engagement he served as Office Engineer in charge of the main office.

In May, 1923, Mr. Whitney again entered the service of the Koppers (H. Koppers) Company, of Pittsburgh, with whom he remained for the next four years. One of these years he served as Field Engineer on the construction of a water-gas plant at Kokomo, Ind.; a by-product coal-gas plant at Fort Wayne, Ind.; and a liquid purification plant for gas at Milwaukee, Wis. During the remaining three years Mr. Whitney was in charge of all foundation and concrete design. Much of his time was devoted to the supervision of design and preparation of plans, specifications, and estimates for structures for the handling and storage of coal, coke, and ashes for by-product coke plants, and other plants constructed by the Koppers Company. Mr. Whitney's knowledge of the latest in engineering procedures—their thorough practical application—and his engineering foresight are indicated in that the specifications for such work, as prepared by Mr. Whitney, are today used by the Koppers Company, as standards.

His next engagement, from November, 1927, to December, 1931, was with the City of Pittsburgh, where he served as Designing Engineer in the Bureau of Bridges and Structures and Assistant Engineer with the City Transit Commission. In this period he was closely connected with the major municipal improvements and in responsible charge of much of the heavy structural design for such projects as the East Street and Aiken Avenue bridges, extension of Mount Washington Roadway and Bigelow Boulevard, and the repairs to several bridges. He also made the preliminary design and estimates for a 500-ft span, reinforced concrete, arch bridge for a proposed extension of the Boulevard of the Allies over Nine-Mile Run. In June, 1932, Mr. Whitney submitted designs and estimates for single-track and double-track sections for proposed municipal subways to the City Transit Commission of Pittsburgh.

From May, 1933, until his death Mr. Whitney was again employed by the U. S. War Department, being attached to the Pittsburgh Engineer District, where he was engaged on general construction, design of river structures, and hydraulic studies pertaining to flood control reservoirs.

John Thad Whitney was an excellent engineer, measured not only by the volume and variety of his technical knowledge or its practical application, but still more by his ability to work with others both as a subordinate and as a superior. He was a man of strong convictions; nevertheless, he conscientiously observed the rights and feelings of others. He was always so tremendously in earnest about everything that he undertook. He had another even more outstanding characteristic in that he lived "with malice toward none." There was nothing petty or mean about him. Few people have been less critical of their fellow beings. His disposition was that of the typical engineer, and his hopes, aspirations, failures, and successes strike a responsive chord with most of us.

John Whitney was a lover of animals, especially horses. He was deeply interested in outdoor life, good literature, music, and poetry. His more harsh commitments were often tempered at the end with some witticism or verse of poetry. He was an ardent student of current events. His personal library of many hundred volumes was very diversified and indicative of a sincere and widely read scholar. In accordance with his wish the technical part of Mr. Whitney's library was given to Norwich University.

He always took a profound interest in the younger engineer. He was willing to assist others in acquiring the engineering information which they desired. He was a virtual encyclopedia for many of his friends and working associates. He would have made an excellent teacher. He had a keen sense of humor, and a rare faculty of enjoying a good joke on himself as well as on the other fellow.

He was a registered engineer in the State of Pennsylvania, a member of the American Legion, and Theta Chi Fraternity. He had long been affiliated with the Methodist Episcopal Church and later became a member of the Mount Lebanon Presbyterian Church, Mount Lebanon, Pa.

Mr. Whitney died in Pittsburgh, Pa., on September 30, 1938. Interment was made in Elmwood Cemetery, in Northfield. He returned from whence he came, to the land he loved so well.

Mr. Whitney was married at Huntington, W. Va., on February 23, 1921, to Mary Wigal who survives. He is also survived by one daughter, Linda Louise Whitney.

Despite his conscientious absorption in his profession he was most devoted to his home and family. His sterling personal character is indicated in his true devotion as a son, husband, father, and friend. In passing he left voids in many lives, never to be filled. However, his memory will have a lasting effect on those who knew him well and now mourn one of earth's gentlemen.

John Thad Whitney was elected a Junior of the American Society of Civil Engineers on April 1, 1914, and an Associate Member on January 19, 1920.

HARRY McKEAN CONNER, Jun. Am. Soc. C. E.[1]

DIED SEPTEMBER 1, 1939

Harry McKean Conner was born at Oakfield, N. Y., on March 1, 1907. His father, H. McKean Conner, a widely known consulting mining engineer, was born at Mauch Chunk, Pa., on March 31, 1875, and died on December 1, 1919. He was a member of the American Institute of Mining and Metallurgical Engineers, a member of the Engineers Club of Northeastern Pennsylvania, and a prominent Mason. He collaborated as an associate editor with Robert Peele in preparing the "Mining Engineers' Handbook" and was responsible for the section dealing with the "Preparation and Coking of Bituminous Coal."

---

[1] Memoir prepared by John C. Buhrendorf and R. B. Strang, Board of Water Supply, Scarsdale, N. Y.

His mother, Sarah G. (Wagner) Conner, born at Newville, Pa., on January 10, 1874, was a daughter of State Senator Samuel C. Wagner and Laura Ege (Woodburn) Wagner. Samuel C. Wagner served as a Captain, during the Civil War, in the Third Pennsylvania Cavalry. Mrs. Conner died at Newville on April 18, 1940.

His uncle was Eli Taylor Conner of Scranton, Pa. Like Harry's father, he was a prominent mining engineer, serving as consulting engineer for the United States Bureau of Mines and as Chairman of the Coal Division of the American Institute of Mining and Metallurgical Engineers.

Harry's youth was spent mainly at Scranton, where he obtained his early education. He was graduated from Central High School, in 1925, having taken a scientific course. Immediately thereafter he secured his first regular employment, and for the thirteen years that followed he worked during the day on engineering projects and pursued engineering studies at night. Due to a change in employment in the summer of 1929 which brought him to New York, N. Y., he was afforded the opportunity of attending the School of Engineering of Columbia University. From this time until his enrollment for the Civil Engineering Degree course at New York University, in New York City, he took extension courses at Columbia pertaining to some of the phases of engineering that were pertinent to his work. Prior to leaving Scranton, he had studied various phases of coal mining as presented by the International Correspondence School. In September, 1931, he enrolled for a degree course in the College of Engineering of New York University. During his attendance at New York University he excelled in all his studies and his brilliant work was recognized by the University when it conferred upon him, in 1937, the degree of Bachelor of Science in Civil Engineering, *cum laude*.

Still in search of further technical knowledge, he enrolled in the Graduate School of the College of Engineering of New York University in September, 1938, for courses leading to a Master's degree in Sanitary Engineering.

On February 4, 1938, he obtained a license to practice Professional Engineering from the University of the State of New York which, previously, on May 11, 1933, had granted him a license to practice land surveying.

With the engineering background furnished by his father and uncle, there was never any question about his vocation in life, and his first practical engineering work started during a summer vacation, in 1924, when he was with a survey party on field work for the Hudson Coal Company, of Scranton, Pa., in connection with anthracite coal mining by the stripping method. After graduation from high school in 1925, he was again engaged by the same company in a similar capacity, and in addition made surveys in their underground mine workings. In September, 1927, he resigned from this firm to join the United Gas Improvement Contracting Company in charge of the surveying on the construction of a plant for the General Electric Company in Philadelphia, Pa. Upon the completion of this work in June, 1928, he became associated with W. W. Young, a consulting engineer of New York City, as an assistant engineer in charge of repairing a sewer system for the Town of Metuchen, N. J. When this project was finished he continued with Mr. Young as an assistant engineer, the next work being for the Westchester County Sanitary Sewer Commission on the preliminary surveys and the construction of sewer trunk lines in Westchester County and on the design of, and specifications for, two sewage disposal plants.

In 1929, he was appointed to the Board of Water Supply of the City of New York on a part of the construction of City Tunnel No. 2. This included the following procedure: A shaft was sunk through earth and rock to a depth of 500 ft, a reinforced concrete caisson being used for the first 100 ft through water-bearing material; then the rock shaft was sunk another 400 ft and lined with concrete; a tunnel, about two miles long, was driven and lined with concrete; the concrete lining of the shaft and tunnel was grouted; and the shaft operating equipment was installed for controlling the flow of water from the tunnel, through the shaft, and into the distribution system. Mr. Conner was in charge of a field survey party on this work until April, 1933, when the project was completed.

From November, 1933, to December, 1936, he was respectively an assistant engineer with the Civil Works Administration (CWA); a section engineer with the Department of Public Welfare; a senior engineer and a supervising engineer with the Works Progress Administration (WPA); and Chief of the Planning Section for the WPA in Bronx County, covering all phases of municipal engineering.

In December, 1936, he was recalled to the Board of Water Supply of New York City to assist in the construction of a portion of the new Delaware Aqueduct System. His first assignment on this project put him in charge of sinking a shaft, 450 ft deep, in rock, lining this shaft with concrete, and driving about 400 ft of tunnel in rock from the bottom of the shaft. In May, 1938, he was appointed assistant section engineer on another contract of the Board of Water Supply which consisted of driving 29,138 ft of deep rock tunnel. He was engaged on this work at the time of his death.

Along with his work during the day and his studies during the evening, Mr. Conner found time to be actively engaged in a wide variety of interests allied to the engineering profession. In 1929 he became a charter member of the New York State Sewage Works Association. While at New York University he was elected to membership in the honorary engineering society of Iota Alpha. On April 21, 1938, he was elected a member of the American Institute of Mining and Metallurgical Engineers. He also served as Secretary and Director of the Bronx County Chapter of Professional Engineers. Upon his graduation from New York University he was appointed the Alumni Member of the University Employment Committee, College of Engineering, and was very active on this committee.

With his varied activities, Harry Conner met a great number of people, and such was his personality that those who were associated with him, both in his work and in his outside interests, became his firm friends, all recognizing the rare combination of ability with the highest personal attributes. His untimely passing deprived the profession of one of its most promising engineers.

On June 27, 1928, Mr. Conner was married to Louise Sanderson Fuller of Scranton, daughter of Ray W. Fuller and Grace (Sanderson) Fuller, and their married life was extremely happy.

Like many men who devote most of their time to solving difficult problems, Mr. Conner derived great pleasure from his camp at Lake Mombasha, New York, where during week ends and vacation periods he partook of the social life of the small community, and attended to a vegetable and flower garden with the aid of his wife. Here he also did odd jobs of carpentry work incidental to making a comfortable lodge.

Harry Conner is survived by his widow and two brothers, William Young Conner and George Wagner Conner.

Mr. Conner was elected a Junior of the American Society of Civil Engineers on November 23, 1931.

FRANKLIN MECHTLEY FELKER, Jun. Am. Soc. C. E.[1]

Died May 29, 1939

Franklin Mechtley Felker was born at Lewistown, Pa., on October 17, 1908, the son of Frank F. and Mary (Mechtley) Felker. He attended the Lewistown grade school and high school. In 1927 he entered the University of Pittsburgh, at Pittsburgh, Pa., to study Civil Engineering, and was graduated in 1931 with the degree of Bachelor of Science. He was a member of Sigma Pi Fraternity. During his college days he worked as transitman for the Standard Steel Company of Burnham, Pa., and worked again for the same firm after graduation. His work as transitman included the laying out of a power plant and annealing furnace, and the mapping of the works and its railroad.

In 1933 he was appointed a junior engineer in the U. S. Forest Service and was assigned to Civilian Conservation Corps (CCC) Camp S58. Later he was transferred to Camp S57. As the man responsible for the engineering work required at these camps, his duties ranged from boundary surveys for the state forest map to construction of camp water supplies, roads, and bridges. During this time he not only endeared himself to the men under him, but impressed the district forester with his efficiency and fitness for his job. In 1936 he was made truck trail locator for twenty of the CCC camps in northern Pennsylvania, a position of considerable responsibility. The following year, when the state was divided into five districts, Mr. Felker was made district engineer of the northern district, with headquarters at Galeton, Pa.

---

[1] Memoir prepared by Charles F. Ruff, M. Am. Soc. C. E.

In April, 1933, he was married to Sarah E. Alexander in Warrenton, Va. Like many another young engineer, Mr. Felker was never able to establish a permanent home but followed the job from Paradise Furnace, Pa., near Camp S57, to Galeton.

In December, 1937, he left the Forest Service to join the newly established Flood Control Bureau of the State of Pennsylvania. Here he was assigned to the hydrologic section, the particular rôle of which was to estimate how large and how often floods might be expected. Besides making valuable contributions to a general study of floods in Pennsylvania, he was also actively engaged on the flood control project for York, Pa., and several other cities in the Susquehanna Basin. Mr. Felker was well liked at the Bureau, both for his unassuming good nature and the quiet efficiency with which he tackled the work in hand.

When the Flood Control Bureau was closed early in 1939, he secured a position as junior engineer with the U. S. Engineer Corps, at Pittsburgh, doing similar work on the Pittsburgh Flood Control Project. He had had this position scarcely a month when a severe cold developed into pneumonia. A week later, on May 29, 1939, he died at Elizabeth Magee Hospital, in Pittsburgh.

The sudden death of this promising engineer, who, despite starting his career during the depression, had managed to keep himself busy and useful, was a great shock to all who knew him. He is survived by his wife and by his mother and father.

Mr. Felker was elected a Junior of the American Society of Civil Engineers on October 26, 1931.

GLENN WILLIAM HOLMES, Jun. Am. Soc. C. E.[1]

Died January 19, 1940

A descendant of a long line of pioneer teachers, engineers, and statesmen, Glenn William Holmes was born in Syracuse, N. Y., on February 1, 1910. His father, Glenn D. Holmes, M. Am. Soc. C. E., was sanitary engineer for the City of Syracuse, and for many years has been engaged in consulting practice in that city. His great-grandfather, Joseph Holmes, was one of the pioneer settlers in western New York; and his grandfather, Joseph W. Holmes, a student of mathematics and astronomy, was the inventor of the Solar Theodolite, the basic principles of which are to be found in the present-day instruments. His mother, Adah (Brett) Holmes, traces her ancestry from the House de la Brette, which produced kings of Navarre, and fought for William the Conqueror in 1066 A.D. Madam Brett, daughter of Francis Rombouts, mayor of the City of New York, N. Y., in 1679, was the first white woman to establish her home (in 1709) in the highlands of the Hudson River. This manor, known as " The Crary House," was later owned and occupied by Robert Fulton Crary, eldest grandson of Robert Fulton and his wife, a descendant of Madam Brett.

---

[1] Memoir prepared by C. E. Ramser, C. S. Jarvis, Members, Am. Soc. C. E., and W. D. Potter, Assoc. M. Am. Soc C. E.

The early boyhood days of Glenn Holmes were spent in Syracuse where he was graduated as an honor student of Central High School. He entered the University of Michigan, at Ann Arbor, Mich., where he pursued an engineering course and received the degree of Bachelor of Science in Civil Engineering in 1932.

With the exception of a summer spent as assistant sanitary inspector for the Lake George Association and a short engagement as assistant engineer for the Onondaga County Sanitary Sewer and Public Works Commission, the first three years of Mr. Holmes' professional career were spent as assistant engineer in his father's office. He assisted in the design and operation of the Newark, New York, Sewage Treatment Plant and conducted various scientific investigations and research, probably the most important of which was his adaptation of the principles of light absorption for the determination of suspended solids in sewage effluent.[2]

In 1934, Mr. Holmes was employed by the firm of Metcalf and Eddy as assistant engineer. He assisted in the preparation of preliminary reports on sewage treatment for various municipalities and more especially in an investigation of the operation of the North Toronto Sewage Treatment Works for the purpose of improving treatment efficiency.

Mr. Holmes resigned from Metcalf and Eddy to take a position in the government service as hydrologist for the newly created Soil Conservation Service, United States Department of Agriculture. While stationed at the operations project of the Service at Bath, N. Y., he conducted the studies reported in an unpublished manuscript entitled " Hydrologic Studies of the July 1935 Flood in South Central New York State." This manuscript later was released to the United States Geological Survey and became the basis for their *Water Supply Paper No. 773–E.*

In November, 1935, he transferred from the Bath project to take a position as assistant, and later as associate hydraulic engineer, on the Washington staff of the Hydrologic Division of the Service. Besides preparing critical reviews of such reports as the State Soil Conservation Programs and the National Resources Committee's Drainage Basin Reports, he was engaged at the time of his death in making a correlation and analysis of hydrologic data collected by the United States Geological Survey on eight of the Demonstration Projects of the Soil Conservation Service.

To all of Mr. Holmes' many friends his philosophy of life was an outstanding characteristic. His fairness in all dealings with his fellow men was an exemplification of the Golden Rule, and his relations as husband and father were always those of the cheerful, loving companion, patient teacher, and guide. In spite of physical handicaps suffered in his early youth, he lived life to its fullest extent up to the very moment of his sudden and untimely death.

---

[2] "Determination of Suspended Solids in Sewage by Light Absorption," by Glenn W. Holmes, *Sewage Works Journal,* July, 1935, pp. 642–657.

On December 22, 1934, he was married to Elma Lyons, who, with two children, Martha and Barbara Jean, survives him. He is also survived by his father and mother, and by his brother, Brett D. Holmes.

Mr. Holmes was a member of the Syracuse South Presbyterian Church. He was also a member of the American Geophysical Union.

Mr. Holmes was elected a Junior of the American Society of Civil Engineers on August 16, 1937.

JOHN MONKS, Affiliate Am. Soc. C. E.[1]

Died October 17, 1939

John Monks was born in New York, N. Y., on October 16, 1864, the son of John Monks and Mary Ann (O'Leary) Monks. He received his education at De LaSalle Institute and Seton Hall College, at South Orange, N. J. Upon leaving college, he entered his father's contracting business which had been established by his grandfather in 1863.

The firm had been largely engaged in building docks about New York harbor, but when his father retired from active participation in the business to accept an appointment from Mayor Strong as dock commissioner, Mr. Monks was elected President of John Monks and Sons and proceeded to extend the firm's activities in other directions. Under the title of General Contractors, the firm specialized in harbor development, and heavy and pneumatic foundations. In record time, the firm built the piers for the landing of the troops of the Spanish-American War, at Montauk Point, Long Island, N. Y., and, upon the invitation of General Alger, then Secretary of War, Mr. Monks visited and advised him regarding the development of the Harbor at San Juan, Puerto Rico.

Under Mr. Monks' direction, the firm also built numerous piers and bulkheads along the Hudson and East rivers, as well as extensive work of the same character in the West Indies. Among the many outstanding structures built by the firm under his régime were the deep pneumatic foundations for the Hecker-Jones-Jewel Mill, pneumatic foundation for the Cincinnati Water Works, foundations for the West Street Building, pneumatic foundations for the Baltimore and Ohio Railroad Bridge over the Susquehanna River at Havre de Grace, Md., and others.

Mr. Monks was also a director in the Old Maine Steamship Line and president of the New York and Baltimore Steamship Company. As a member of the Chamber of Commerce of the State of New York, he took an active interest in civic affairs.

---

[1] Memoir prepared by Emott D. Buel, M. Am. Soc. C. E.

Because of ill health, he was forced, in 1905, to relinquish active participation in the contracting business. He entrusted the business to his brothers, but retained his position as president of the firm and acted in an advisory capacity in all matters of importance. In the meantime, he traveled extensively in Europe and South America and, in 1916, believing his health sufficiently restored, resumed his former duties.

Unfortunately, in late years, his health failed him completely, and in 1932 he was compelled to retire from the firm, his clubs, and all social activities. He spent the last few years of his life on his country estate at East Hampton, Long Island, N. Y., where he had collected a very fine library. He found one of his greatest pleasures among his books.

He was a member of the Metropolitan Club of Washington, D. C., the American Geographic Society, and the National Audubon Society. Until his retirement, he had been a member of the Racquet and Tennis Club, the Manhattan Club, the Grolier Club, the Downtown Association, and the Long Island Country Club. Mr. Monks was greatly beloved by his friends and known as a man of high ideals and unswerving integrity.

He was married to Alice Parsons in 1903, and is survived by his son, John Monks, Jr., and three brothers, Richard A., Robert, and Jerome Monks.

On the evening of October 17, 1939, Mr. Monks suffered a heart attack and passed away peacefully.

Mr. Monks was elected an Affiliate of the American Society of Civil Engineers on May 31, 1898.

LOUIS ALOYSIUS SLATTERY, Affiliate Am. Soc. C. E.[1]

Died February 24, 1939

Louis Aloysius Slattery was born in Chatham, N. Y., on May 12, 1887, the son of John Slattery and Mary (Gilmore) Slattery. He came to New York, N. Y., when still a boy and received his early education in the public schools of Manhattan.

In 1904 he entered the employment of the J. C. Rodgers Contracting Company as a timekeeper and material checker. Later he was connected with the contracting organization of Rogers and Hagerty, Incorporated, in the same capacities. During his period of employment with the latter company, he advanced to the position of assistant superintendent.

In September, 1913, he accepted the position of assistant superintendent of construction with the U. S. Realty and Improvement Company on the construction of a section of the Brooklyn-Manhattan Transit subway along Broadway, from West 28th Street to West 38th Street, New York.

During the World War Mr. Slattery was superintendent of construction with the Federal Shipbuilding Company at Kearney, N. J. In this position he did outstanding work in the erection of shipways, docks, machine foundations, and industrial buildings incidental to a large shipbuilding yard.

---

[1] Memoir prepared by Walter Caccia, Assoc. M. Am. Soc. C. E.

From January, 1920, to January, 1922, he was engaged by the Frederick Snare Corporation as superintendent of construction in the building of the Hunters Brook, Turkey Mountain, and Indian Brook siphons for the New York Board of Water Supply. Following this assignment he returned to New York and took charge of foundations, fill, and grading of the Interborough Rapid Transit subway storage yard on Westchester Avenue, Borough of the Bronx, for the P. T. Cox Company, Inc. He had essentially completed this work when the D. C. Serber Company, Inc., of New York was awarded the contract for the erection of the car barns, storage yard facilities, and steel elevated railroad structure in the same yard. Mr. Slattery took charge of this work for the Serber Company and completed it successfully.

In July, 1925, Mr. Slattery and Martin J. Lyons organized their own contracting organization under the name of Lyons-Slattery Company, Inc. As construction manager, Mr. Slattery took an active part in all field operations, in addition to his duties as secretary and treasurer of this organization.

Some of the outstanding contracts prosecuted by the Lyons-Slattery Company, Inc., included the bridges and decked areas of Fordham Plaza over the Harlem Division tracks of the New York Central Railroad in the Borough of the Bronx; the elimination of the New York Central grade crossing at Dyckman Street, Borough of Manhattan; and the elimination of a grade crossing on the Putnam Division of the New York Central Railroad at Nepperhan Heights, N. Y. Following these contracts, the Lyons-Slattery Company was awarded the contract for Section 5, Route 106, of the Grand Boulevard and Concourse Rapid Transit subway, extending from 183d Street to Kingsbridge Road in the Borough of the Bronx. This contract was completed successfully and considerable credit must be given to Mr. Slattery for the expeditious manner in which the work was done.

In May, 1931, Mr. Slattery participated in the formation of the Hudson River Stone Corporation with Mr. Lyons and the executives of the O'Brien Brothers, Inc., wholesale producers and distributers of sand and gravel in New York. As vice-president and general manager of this new organization, he was in responsible charge of the construction and operation of the company's quarry and crushing plant at Coldspring, N. Y., from the time of formation of the Company until the late fall of 1938, when a cardiac condition became too critical to permit him to continue his work.

Mr. Slattery possessed an unusual faculty in solving the various problems of construction work; he had a natural ability for leading men and selecting his staff executives. His personality drew his associates into a close relationship and encouraged them to give to their work the best they had to offer.

He died on February 24, 1939, in New York, and is survived by his wife, the former Maud Kamper.

Mr. Slattery was elected an Affiliate of the American Society of Civil Engineers on July 6, 1936.

GEORGE OLIVER TENNEY, Affiliate Am. Soc. C. E.[1]

Died November 6, 1938

George Oliver Tenney, the son of Charles B. and Abby (Lerned) Tenney, was born in Littleton, Mass., on September 11, 1861.

His long and brilliant career in engineering and construction began at the early age of sixteen when he was employed by the City Engineer of the City of Somerville, Mass. His early ability and hard study are attested by the fact that after three years in the City Engineer Department of Somerville, as Rodman and Inspector on Sewer Work, he was given a position, in 1880, as Assistant Engineer, by the New York, West Shore and Buffalo Railway Company. Mr. Tenney had remarked he was once the youngest member of a field party of which he was in charge. In 1883 he returned to the City of Somerville as Assistant Engineer, where he remained until 1886.

About this time the City of Decatur, Ala., became the center of what Mr. Tenney described as the "Alabama Boom." He accepted a position as Assistant Engineer on Sewer Construction for the City of Decatur in 1886 and remained there until 1892. It was here that he gave up his engineering practice to enter the contracting field on sewer construction in which he continued successfully in Decatur until the yellow fever epidemic, which caused the overnight abandonment of all construction activities and a general exodus from the city.

Continuing in the contracting field, he formed a partnership (Crass and Tenney) in 1892, and was engaged in the construction of the Chickamauga National Park, Chattanooga, Tenn., for the United States National Park Commission. On completion of this work, about 1895, he moved to Spartanburg, S. C., and engaged in the construction of dams. Among those constructed were six at the following points: Clifton, Greenville, Portman Shoals, and Neil Shoals, in South Carolina, and McAdenville and Harden in North Carolina.

He continued in this work until 1906, when the Atlantic Bitulithic Company was organized by Warren Brothers Company of Boston, Mass., for street and road construction in the South. Mr. Tenney was made President at its organization and so continued, for a third of a century, until his death. Under his direction many of the important streets in cities throughout the South Atlantic States have been constructed.

His honesty and fairness were recognized throughout the country, by both his fellow contractors and the officials for whom the work was performed. His contribution to the industry, in this respect, is priceless. His ability to organize was remarkable, as was the loyalty he received from his employees.

He is survived by his widow, Mrs. Minna L. Tenney, to whom he was married on February 2, 1929.

Mr. Tenney was elected a Junior of the American Society of Civil Engineers on September 7, 1887, and an Affiliate on February 5, 1901.

---

[1] Memoir prepared by M. J. Johnson, Pres., Atlantic Bitulithic Co., Washington, D. C.

TRANSACTIONS

AMERICAN SOCIETY OF CIVIL ENGINEERS

INDEX

VOLUME 105

1940

Subject Index, Page 2030

Author Index, Page 2041

Titles of papers are in quotation marks when given with the author's name.

VOLUME 105

SUBJECT INDEX

ACCIDENTS.

Stopping the increase in night accidents. 326.

ADDRESSES.

Presidential Address at the Annual Convention at Denver, Colorado, July 24, 1940. John P. Hogan. 1781.

ALUMINUM.

"Tests on Built-Up Columns of Structural Aluminum Alloys." Marshall Holt. (With Discussion.) 196.

AQUEDUCTS.

See **PIPE LINES.**

BEACHES.

See **SHORE PROTECTION.**

BORINGS.

Interpretation of borings. 455.

"Large Core Drills Aid Construction at Chickamauga Dam." James S. Lewis, Jr. (With Discussion.) 850.

BOUNDARIES.

Boundary location. 733.

BRACING.

"Wind Bracing in Steel Buildings." Final Report of Sub-Committee No. 31, Committee on Steel, of the Structural Division. 1713.

BRIDGES.

"Reconstruction of the Walpole-Bellows Falls Arch Bridge." H. E. Langley and Edward J. Ducey. 1675. Discussion: J. B. French, Lewis D. Rights, Conde B. McCullough, and H. M. Nelson. 1701.

BUILDINGS.

"Settlement Studies of Structures in Egypt." Gregory P. Tschebotareff. (With Discussion.) 919.

"Simplified Wind-Stress Analysis of Tall Buildings." Otto Gottschalk. (With Discussion.) 1019.

"Wind Bracing in Steel Buildings." Final Report of Sub-Committee No. 31, Committee on Steel, of the Structural Division. 1713.

"Wind Forces on a Tall Building." J. Charles Rathbun. (With Discussion.) 1.

BULKHEADS.

Design for a simple bulkhead. 885.

CHANNELS.

"Design of an Open-Channel Control Section." Karl R. Kennison. (With Discussion.) 744.

"Lateral Spillway Channels." Thomas R. Camp. (With Discussion.) 606.

COLUMNS.

Relative resistance values of building columns to unit lateral displacement. 1031.

Special treatment of nose pier. 863.

"Tests on Built-Up Columns of Structural Aluminum Alloys." Marshall Holt. 196. Discussion: Alfred S. Niles. 218.

CONSTRUCTION PLANT.

See **CONTRACTOR'S PLANT.**

CONTRACTOR'S PLANT.

"Reconstruction of the Walpole-Bellows Falls Arch Bridge." (With Discussion.) 1675.

CONTRACTS.

"The Risk of the Unexpected in Sub-Surface Construction Contracts." Oren Clive Herwitz. 454. Discussion: Alonzo J. Hammond, Frederick W. Newton, David A. Molitor, F. B. Marsh, Evan S. Martin, C. Maxwell Stanley, Francis J. Morgan, Frederick C. Zeigler, Lazarus White, T. Kennard Thomson, and Carroll A. Farwell. 476.

COSTS OF WORK.

Cost of main sewage pumping station and sewage treatment plant. 1622.

Cost of treatment works for Boston sewerage system. 1007.

DAMS.

"Engineering Geology Problems at Conchas Dam, New Mexico." Irving B. Crosby. 581. Discussion: H. L. Johnson. 600.

"Graphical Arch Analysis Applicable to Arch Dams." Carl H. Heilbron, Jr., and William H. Saylor. 765. Discussion: I. M. Nelidov. 790.

"Large Core Drills Aid Construction at Chickamauga Dam." James S. Lewis, Jr. 850. Discussion: J. B. Newsom, J. G. Tripp, James B. Hays, and O. N. Floyd. 865.

Trends in dam construction (earth, masonry, rock-fill) 1930–1939. 1744.

DOWEL BARS.

"Design of Dowels in Transverse Joints of Concrete Pavements." Bengt F. Friberg. (With Discussion.) 1076.

DRILLING.

"Large Core Drills Aid Construction at Chickamauga Dam." James S. Lewis, Jr. (With Discussion.) 850.

EARTH PRESSURES.

"Field Test of a Shale Foundation." August E. Niederhoff. (With Discussion.) 1519.

EARTHQUAKES.

"Earthquakes and Structures." Leander M. Hoskins and John D. Galloway. 269. Discussion: Homer M. Hadley, R. McC. Beanfield, R. S. Chew, Jacob J. Creskoff, Arthur C. Ruge, Walter L. Huber, A. A. Eremin, Henry D. Dewell, and Lydik S. Jacobsen. 298.

ENGINEERS AND ENGINEERING.

"The Relation of the Society to National Defense." Address at the Annual Convention, Denver, Colorado, July 24, 1940. John P. Hogan.

EROSION.

"Beach Erosion Studies." Earl I. Brown. (With Discussion.) 869.

Control of soil erosion along Yellow River. 407.

EVAPORATION.

"Hydrology of the Great Lakes": A Symposium. C. R. Pettis and Harold C. Hickman. 794. Discussion: A. A. Young, Alfred J. Cooper, Jr., Adolph F. Meyer, S. T. Harding, O. E. Meinzer, R. W. Davenport, and G. H. Hickox. 818.

FILTRATION.

Progress in water treatment and filtration in the decade, 1930–1939. 1775.

FLANGES.

Flange stresses measured. 1470.

FLASH BOARDS.

"Flash-Board Pins." Chilton A. Wright and Clifford A. Betts. 1412. Discussion: William P. Creager, Lincoln W. Ryder, E. T. Schuleen, John E. Field, Julian H. White, and Harry H. Hatch. 1445.

FLOODS.

Outline of floods in U. S. during decade from 1930 to 1939. 1741.

"The Yellow River Problem." O. J. Todd and S. Eliassen. (With Discussion.) 346.

Use of the unit hydrograph in estimating flood flows. 1175.

FOUNDATIONS.

"Engineering Geology Problems at Conchas Dam, New Mexico." Irving B. Crosby. (With Discussion.) 581.

"Field Tests of a Shale Foundation." August E. Niederhoff. 1519. Discussion: Harry H. Hatch, Jacob Feld, and Jack R. Rountree. 1535.

"Large Core Drills Aid Construction at Chickamauga Dam." James S. Lewis, Jr. (With Discussion.) 850.

"Settlement Studies of Structures in Egypt." Gregory P. Tschebotareff. 919. Discussion: L. C. Wilcoxen, Trent R. Dames, Edwin J. Beugler, W. S. Hanna, and D. P. Krynine. 946.

"The Risk of the Unexpected in Sub-Surface Construction Contracts." Oren Clive Herwitz. (With Discussion.) 454.

FRICTION.

Correction for friction in open-channel control section. 747.

Experimental evaluation of friction factor in lateral spillway channels. 614.

GAGES.

Measuring wind pressure on a tall building. 14.

See also **METERS.**

GEODESY.

"Combining Geodetic Survey Methods with Cadastral Surveys." Carl M. Berry. 1300. Discussion: William L. Sawyer, Philip Kissam, and Gordon Macleish. 1331.

Establishing a system of rectangular coordinates. 534.

GEOLOGY.

"Engineering Geology Problems at Conchas Dam, New Mexico." Irving B. Crosby. (With Discussion.) 581.

GIRDERS.

"Effective Moment of Inertia of a Riveted Plate Girder." Scott B. Lilly and Samuel T. Carpenter. 1462. Discussion: William R. Osgood, Clyde T. Morris, B. R. Leffler, E. Neil W. Lane, Lewis E. Moore, W. E. Black, L. E. Grinter, Charles M. Spofford, E. Mirabelli, Edward Godfrey, Walter H. Weiskopf, C. D. Williams, Alvin B. Auerbach, Jonathan Jones, R. L. Moore, J. M. Garrelts, I. E. Madsen, Francis P. Witmer, A. W. Fischer, J. R. Shank, Harold D. Hussey, Charles U. Kring, and Thomas C. Shedd. 1477.

GRAPHICAL CHARTS.

"Graphical Arch Analysis Applicable to Arch Dams." Carl H. Heilbron, Jr., and William H. Saylor. (With Discussion.) 765.

GROUND-WATER.

Progress in knowledge of ground-water, 1930–1939. 1754.

HARBORS.

Great Lakes harbors. 172.

"Pollution of Boston Harbor." Arthur D. Weston and Gail P. Edwards. (With Discussion.) 973.

HIGHWAYS.

Highway developments in the United States. 222.

HYDRO-ELECTRIC POWER PLANTS.

See **POWER PLANTS.**

INSTRUMENTS.

Experiment visualizing the direction of column reactions. 1026.

IRRIGATION.

"Development of the Colorado River in the Upper Basin." Thomas C. Adams. (With Discussion.) 1345.

LAW.
  "Proposed Improvements for Land Surveys and Title Transfers." Philip Kissam. (With Discussion.) 731.
  The land court and its engineering procedure. 554.
  "The Risk of the Unexpected in Subsurface Construction Contracts." Oren Clive Herwitz. (With Discussion.) 454.

LEVEES.
  Earth dikes on the Yellow River. 391.

LEVELING.
  "An Improved Method for Adjusting Level and Traverse Surveys." Clarence Norris and Julius L. Speert. 1376. Discussion: George H. Dell, Howard S. Rappleye, R. M. Wilson, Cleveland B. Coe, George D. Whitmore, C. C. Miner, W. O. Byrd, and Robert C. Sheldon. 1395.

MATERIALS OF CONSTRUCTION.
  See **ALUMINUM.**

MEMOIRS OF DECEASED MEMBERS.
  See name of member in Author Index.

METERS.
  Types of water meters in use, 1930–1939. 1769.

MODELS.
  Model of Empire State Building used in wind pressure studies. 32.

NATIONAL DEFENSE.
  "The Relation of the Society to National Defense." Address at the Annual Convention, Denver, Colorado, July 24, 1940. John P. Hogan. 1781.

NAVIGATION.
  Improvement of navigation on the Yellow River. 412.

PAVEMENT.
  "Design of Dowels in Transverse Joints of Concrete Pavements." Bengt F. Friberg. 1076. Discussion: L. E. Grinter, and W. O. Fremont. 1096.

PHOTOELASTICITY.
  Photoelastic study of stress distribution around a tunnel. 1149.
  "Specification and Design of Steel Gusset-Plates." T. H. Rust. (With Discussion.) 142.

PIPE LINES.
  Trends in construction of pipe lines, 1930–1939. 1756.

POWER PLANTS.
  The Yellow River power developments at Hu-kou Falls. 409.

PUBLIC UTILITIES.
  Trends in valuation of utilities. 1778.

PUMPS AND PUMPING.

Ten years' progress in centrifugal pumps. 1771.

RAILROADS.

"Transportation Developments in the United States." Fred Lavis. (With Discussion.) 220.

RAINFALL.

"Analysis of Run-Off Characteristics." Otto H. Meyer. 83. Discussion: Victor H. Cochrane, Bertram S. Barnes, LeRoy K. Sherman, Richmond T. Zoch, Merrill Bernard, Franklin F. Snyder, W. G. Hoyt, C. O. Clark, C. S. Jarvis, and Howard M. Turner. 101.

Effect of storms on quantity of suspended solids in sewage. 1610.

"The Unit Hydrograph Principle Applied to Small Water-Sheds." E. F. Brater. 1154. Discussion: Franklin F. Snyder, LeRoy K. Sherman, Raphael G. Kazmann, and Waldo E. Smith. 1179.

REINFORCED CONCRETE.

"Design of Circular Concrete Tanks." George S. Salter. (With Discussion.) 504.

"Design of Dowels in Transverse Joints of Concrete Pavements." Bengt F. Friberg. (With Discussion.) 1076.

REPORTS OF COMMITTEES.

"Important Events, Developments, and Trends in Water Supply Engineering During the Decade Ending With the Year 1939." Report of the Committee on Water Supply of the Sanitary Engineering Division. F. A. Barbour, J. R. Baylis, W. W. Brush, L. R. Howson, J. A. Wade, and Thomas H. Wiggin. 1740.

"Wind Bracing in Steel Buildings." Final Report of Sub-Committee No. 31, Committee on Steel, of the Structural Division. Clyde T. Morris, N. A. Richards, Francis P. Witmer, and C. R. Young. 1713.

RESERVOIRS.

"Functional Design of Flood Control Reservoirs." C. J. Posey and Fu-Te I. 1638. Discussion: Edward Soucek, J. C. Stevens, Edward J. Bednarski, Roland A. Kampmeier, Edgar E. Foster, Sherman M. Woodward, M. Kindinger, P. Wilhelm Werner, Waldo E. Smith, J. O. Jones, and W. C. Hammatt. 1648.

RIVERS.

"Development of the Colorado River in the Upper Basin." Thomas C. Adams. 1345. Discussion: C. C. Elder. 1366.

"The Yellow River Problem." O. J. Todd and S. Eliassen. 346. Discussion: J. W. Beardsley, Elliott J. Dent, Herbert Chatley, H. van der Veen, C. S. Jarvis, E. W. Lane, and George Higgins. 417.
